Accepted 3 February 2014

ABSTRACT

Protecting the health of the athlete is a goal of the International Olympic Committee (IOC). The IOC convened an expert panel to update the 2005 IOC Consensus Statement on the Female Athlete Triad. This Consensus Statement replaces the previous and provides guidelines to guide risk assessment, treatment and return-to-play decisions. The IOC expert working group introduces a broader, more comprehensive term for the condition previously known as 'Female Athlete Triad'. The term 'Relative Energy Deficiency in Sport' (RED-S), points to the complexity involved and the fact that male athletes are also affected. The syndrome of RED-S refers to impaired physiological function including, but not limited to, metabolic rate, menstrual function, bone health, immunity, protein synthesis, cardiovascular health caused by relative energy deficiency. The cause of this syndrome is energy deficiency relative to the balance between dietary energy intake and energy expenditure required for health and activities of daily living, growth and sporting activities. Psychological consequences can either precede RED-S or be the result of RED-S. The clinical phenomenon is not a 'triad' of the three entities of energy availability, menstrual function and bone health, but rather a syndrome that affects many aspects of physiological function, health and athletic performance. This Consensus Statement also recommends practical clinical models for the management of affected athletes. The 'Sport Risk Assessment and Return to Play Model' categorises the syndrome into three groups and translates these classifications into clinical recommendations.

INTRODUCTION

Protecting the health of the athlete is one of the goals of the International Olympic Committee (IOC).¹ The Olympic Movement Medical Code, which governs the actions of the IOC Medical Commission and sport organisations, also emphasises the importance of protecting the health of the athlete.² In 2005, the IOC published the Consensus Statement (Consensus Statement) and the IOC Position Stand (Position Stand)³ on the Female Athlete Triad.⁴ Based on scientific evidence published in the intervening period, this Consensus Statement serves to update and replace these documents and provide guidelines to the athlete health support team to guide risk assessment, treatment and return-to-play decisions for affected athletes.

Relative energy deficiency in sport

In the 2005 IOC Consensus Statement,⁴ the Female Athlete Triad (Triad) was defined as 'the combination of disordered eating (DE) and irregular menstrual cycles eventually leading to a decrease in endogenous oestrogen and other hormones, resulting in low bone mineral density' (BMD) based on the original scientific evidence of Drinkwater *et al.*⁵ In 2007, following progress in scientific understanding, the American College of Sports Medicine redefined the Triad as a clinical entity that refers to the 'relationship between three inter-related components: energy availability (EA), menstrual function and bone health'. Added was an understanding of the pathophysiology describing the concept that over a period of time, the athlete moves along on a continuous spectrum ranging from the healthy athlete with optimal EA, regular menses and healthy bones to the opposite end of the spectrum characterised by amenorrhoea, low EA and osteoporosis.⁶

Since 2007, scientific evidence and clinical experience show that the aetiological factor underpinning the Triad is an energy deficiency relative to the balance between dietary energy intake (EI) and the energy expenditure required to support homeostasis, health and the activities of daily living, growth and sporting activities. It is also evident that the clinical phenomenon is not a triad of three entities of EA, menstrual function and bone health, but rather a syndrome resulting from relative energy deficiency that affects many aspects of physiological function including metabolic rate, menstrual function, bone health, immunity, protein synthesis, cardiovascular and psychological health. In addition, it is evident that relative energy deficiency also affects men. Therefore, a new terminology is required to more accurately describe the clinical syndrome originally known as the Female Athlete Triad. Based on its interdisciplinary expertise, the IOC Consensus group introduces a more comprehensive, broader term for the overall syndrome, which includes what has so far been called the 'Female Athlete Triad': *Relative Energy Deficiency in Sport (RED-S)*.

The syndrome of RED-S refers to impaired physiological function including, but not limited to, metabolic rate, menstrual function, bone health, immunity, protein synthesis, cardiovascular health caused by relative energy deficiency.

CrossMark

To cite: Mountjoy M, Sundgot-Borgen J, Burke L, *et al.* *Br J Sports Med* 2014;**48**:491–497.

The underlying problem of RED-S is an inadequacy of energy to support the range of body functions involved in optimal health and performance. EA is calculated as EI minus the energy cost of exercise relative to fat-free mass (FFM) and in healthy adults, a value of 45 kcal/kg FFM/day equates energy balance.⁷ Low EA, which occurs with a reduction in EI and/or increased exercise load, causes adjustments to body systems to reduce energy expenditure, leading to disruption of an array of hormonal, metabolic and functional characteristics.⁷ DE underpins a large proportion of cases of low EA, but other situations, such as a mismanaged programme to quickly reduce body mass/fat or an inability to track EI with an extreme exercise commitment, may occur without such a psychological overlay.⁷

Although the literature on low EA has focused on female athletes, it has also been reported to occur in male athletes.⁸ Prevalence studies of low EA in male athletes have been few, however, low EA appears to occur among the same at risk sports as for female athletes: the weight sensitive sports in which leanness and/or weight are important due to their role in performance, appearance or requirement to meet a competition weight category.⁸

Although simple messages about optimal, tolerable and unsafe levels of EA have been provided⁹ there are some caveats in the science. First, the complex dose–response relationship between reduction in EA and the disruption of various hormones¹⁰ and bone formation markers¹¹ vary in nature and thresholds. Therefore, the cost of any energy mismatch should be carefully considered before it is implemented. A second caveat is that it is now known that the resting metabolic rate in athletes of small body size is underestimated in the linear scaling of EA relative to LBM/FFM.¹² Finally, findings from laboratory settings may not apply as cleanly to free-living athletes. Numerous studies in female athletes have failed to find clear thresholds or associations between field determinations of low EA and objective measures of energy conservation such as metabolic hormones¹³ and menstrual disturbances.¹⁴ It is possible that other factors seen in free-living populations such as psychological stress, greater variability in between-day and within-day energy deficiency or dietary characteristics interact with each other to alter the effects of low EA.

Disordered eating

The disordered eating (DE) continuum starts with appropriate eating and exercise behaviours, including healthy dieting and the occasional use of more extreme weight loss methods such as short-term restrictive diets (<30 kcal/kg FFM/day).¹⁵ The continuum ends with clinical eating disorders (EDs), abnormal eating behaviours, distorted body image, weight fluctuations, medical complications and variable athletic performance. The Diagnostic and Statistical Manual of Mental Disorders (DSM-5) diagnostic classifications for EDs include anorexia nervosa, bulimia nervosa, binge ED and other specified and unspecified feeding or ED.¹⁶ These EDs have many features in common, and athletes frequently move among them.⁸ The pathogenesis of EDs is multifactorial with cultural, familial, individual and genetic/biochemical factors playing roles.¹⁷ In addition, factors specific to sport such as dieting to enhance performance, personality factors, pressure to lose weight, frequent weight cycling, early start of sport-specific training, overtraining, recurrent and non-healing injuries, inappropriate coaching behaviour and regulations in some sports have been suggested.⁸ The prevalence of DE is about 20% and 13% among adult and adolescent female elite athletes, and 8% and 3% in adult and adolescent

male elite athletes, respectively.^{15–18} The prevalence differs significantly among sports.¹⁵

Hormonal and metabolic imbalance

Eumenorrhea is defined as regular cycles occurring at intervals between 21 and 35 days. In adolescents, the cycles range between 21 and 45 days.¹⁹ Primary amenorrhoea is defined as no menarche by age 15 years.²⁰ Secondary amenorrhoea refers to an absence of three consecutive cycles post-menarche. Oligomenorrhoea is defined as a cycle length greater than 45 days. Estimates of the prevalence of menstrual disorders in athletes vary widely.²¹ Secondary amenorrhoea prevalence is estimated in collegiate women from 2% to 5% and as high as 69% in dancers²² and 65% in long-distance runners.²³ Primary amenorrhoea in collegiate athletes was found to be 7% overall, and was higher (22%) in cheerleading, diving and gymnastics.²⁴ Subtle menstrual dysfunction, such as very light bleeding, mildly extended menstrual interval and premenstrual and postmenstrual spotting may occur, and may be underestimated by routine screening.²⁵

Abnormal levels of hormones,²⁶ LH pulsatility, inadequate body fat stores, low EA and exercise stress may be aetiological factors in menstrual disorders in athletes. Marked reduction in EA may disrupt the LH pulsatility by affecting the hypothalamic hormone gonadotropin-releasing hormone output²⁷ which subsequently alters the menstrual cycle. This is known as *Functional Hypothalamic Amenorrhea* (FHA). Rapid or significant fat mass reduction, even over as short as a 1-month period, may compromise menstrual function. Low EA alters levels of metabolic hormones and substrates, for example, insulin, cortisol, growth hormone, insulin-like growth factor-I (IGF-I), 3,3,5-triiodothyronine, ghrelin, leptin, peptide tyrosine-tyrosine, glucose, fatty acids and ketones.²⁸

Health and performance consequences of RED-S

RED-S can have serious implications for many body systems, resulting in short-term and long-term compromise of optimal health and performance. Athletes who suffer from long-term low EA may develop nutrient deficiencies (including anaemia), chronic fatigue and increased risk of infections and illnesses, all of which have the potential to harm health and performance.⁶ Physiological and medical complications involve the cardiovascular, gastrointestinal, endocrine, reproductive, skeletal, renal and central nervous systems.⁶ Psychological stress and/or depression can result in low EA and EDs and can also be a result of low EA.¹⁷ Research indicates that muscle protein synthesis is reduced even at EA of 30 kcal/kg FFM/day.²⁹ Low EA causes unfavourable lipid profiles and endothelial dysfunction, thereby increasing cardiovascular risk.³⁰ Hormonal and metabolic abnormalities caused by RED-S and carbohydrate deficiency can result in a reduction in glucose utilisation, mobilisation of fat stores, slowing of metabolic rate and a decreased production of growth hormone.³¹

Irregular or absent menses may have significant emotional impact creating anxiety and an altered perception of self-normalcy.³² It may also confound conception, leading to unexpected pregnancy as well as inaccurate dating of pregnancy. Long-term reproductive repercussions of RED-S for women and men are unknown.

RED-S also has adverse health consequences for bone. Peak bone mass occurs around 19 years in women and 20.5 years in men.³³ Oestrogen increases uptake of calcium into blood and deposition into bone, while progesterone facilitates the actions of oestrogen through multiple complex mechanisms.³⁴ Even silent oestrogen/progesterone imbalance, as seen in subclinical

ovulatory disturbances with low EA may produce negative changes in bone.³⁵ In men and women, testosterone has anabolic effects on bone, stimulating osteoclasts and increasing bone formation and calcium absorption.³⁶ Low-testosterone levels have been associated with low BMD in male athletes.³⁷ Endogenous oestrogens and androgens have independent effects on bone development in both sexes.^{38, 39} Increases in the stress hormones, catecholamines and cortisol, concomitant with low EA, have a negative effect.⁴⁰ The bones of athletes with chronic amenorrhoea, benefit less from the osteogenic effects of exercise.⁴¹ Although low BMD was first attributed to hypoestrogenism of menstrual dysfunction, low EA is now recognised as an independent factor of poor bone health at all levels of energy deficiency due to decreased IgF-1 and bone formation markers levels.⁴² Bone loss in these athletes may be irreversible.⁴³

Changes in bone structure lead to an increased risk of stress fractures.⁴⁴ Dietary insufficiencies increase the risk of stress fractures in both sexes.^{45, 46} Additional risk factors include menstrual dysfunction,⁴⁷ compulsive exercise, underlying poor bone health^{48, 49} low body mass index, prior fracture⁵⁰ and eating psychopathology.^{49–51} High-risk stress fractures (ie, femoral neck) occur in adolescent athletes with the RED-S, and can have serious long-term consequences^{52, 53} (figure 1). RED-S can also affect athletic performance. Functional impairments associated with low energy availability include a greater prevalence of viral illnesses,⁵⁵ injuries⁵⁶ and most critically reduced responsiveness to training and subsequent performance.⁵⁷ Further studies of performance effects of low energy availability are likely to provide significant incentive to change damaging behaviours. Such studies should confirm under which situations these effects occur (figure 2). In addition, some athletes with disordered eating/eating disorders practise extreme weight control methods (fasting, vomiting, diuretic and laxative abuse) that have possible health and performance consequences such as dehydration and

Figure 1 Health Consequences of Relative Energy Deficiency in Sport (RED-S) showing an expanded concept of the Female Athlete Triad to acknowledge a wider range of outcomes and the application to male athletes (*Psychological consequences can either precede RED-S or be the result of RED-S). Adapted from Constantini.⁵⁴

Figure 2 Potential Performance Effects of Relative Energy Deficiency in Sport (*Aerobic and anaerobic performance). Adapted from Constantini.⁵⁴

electrolyte imbalances, and gastrointestinal problems, including esophagitis and oesophageal perforation from vomiting. Diuretics and some diet pills may contain WADA prohibited substances.⁵⁸

Male athletes

Although there is a dearth of prevalence studies in low EA in male athletes, Vogt *et al*⁵⁹ showed that male cyclists had severely reduced EA of 8 kcal/kg/FFM/day and Müller *et al*⁶⁰ have reported high prevalence of underweight international level ski jumpers. Although male athletes are at lower risk for developing DE/ED^{8, 18, 61} the prevalence in elite male athletes is high in cycling (50%),⁶² gravitational (24%) and weight class sports (18%).¹⁵ DE/EDs in male jockeys are associated with low BMD.⁶³ Even in the absence of DE/EDs, male endurance athletes in running^{37, 64, 65} and in non-weight bearing sports such as cycling,^{66–69} are at high risk for low BMD. Low EA alters endocrine function¹¹ and direct and indirect impacts on bone may occur in male athletes.⁷⁰

Athletes of non-caucasian ethnicity

The prevalence of low EA has been studied mainly in females of Caucasian, European or European American descent. Whether race plays a role in the incidence and underlying aetiology of the RED-S remains speculative.

Race is a significant variable for several of the individual Triad components in non-athletic women. For example, a lower risk of ED is shown in African-American than Caucasian women,⁷¹ even among adolescent athletes.⁷² Whether the prevalence of menstrual disorders differs among racially diverse, athletic groups is currently unknown. In non-athletes, menarche occurs significantly earlier in African-American than in Caucasian or European American women.⁷³ The BMD of African-American non-athletic females is significantly greater than that of Caucasian women, with a lower risk of osteoporosis and fracture.⁷⁴ In athletes, little is known

about the differences in BMD among ethnic groups, especially in the presence of low EA, DE/EDs and hormonal and metabolic imbalances. Stress fractures in African-American military recruits are lower than in Caucasian recruits.⁷⁵ Based on preliminary data of a multicentre study, African-American and African black athletes exhibit similar symptoms of low EA, with Caucasian athletes showing greater risk of DE/EDs and menstrual dysfunction⁷⁶ and no advantage for BMD in African black athletes.⁷⁷ There are no published scientific studies in Hispanic and limited evidence on Asian athletes.⁷⁸

Athletes with a disability

At present there are no data available on low EA in athletes with disabilities. Individuals with spinal cord injuries, suffer from osteoporosis due to the lack of skeletal loading.⁷⁹ While no data exist on EA or DE/ED patterns in athletes with a disability, their occurrence should not be overlooked. RED-S in athletes with a disability should be taken seriously due to possible comorbidities. Athletes with an amputation and who ambulate may have additional energetic challenges due to the inefficiency of movement,⁸⁰ thus increasing their risk for inadvertent energy deficiency.⁸¹

Screening and diagnosis

Relative energy deficiency and EDs in sport

The screening and diagnosis of RED-S is challenging, as symptomatology can be subtle. A high index of suspicion of the athlete at risk is needed. Early detection is crucial to improve performance and prevent long-term health consequences. Screening for RED-S should be undertaken as part of an annual Periodic Health Examination (PHE) and when an athlete presents with DE/ED, weight loss, lack of normal growth and development, menstrual dysfunction, recurrent injuries and illnesses, decreased performance or mood changes. Although various screening instruments exist,^{16 82 83} they have not been validated and there is no consensus on which screening tool has the best efficacy.^{84 85} Furthermore, these tools exclude men, disabled athletes and are not ethnically diverse.

Since low EA plays a pivotal role in the development of the RED-S, diagnosis should focus on identification of the presence and causes of the low EA. Unfortunately, there are no standardised guidelines to determine EA. EA is equivalent to EI minus the cost of exercise energy expenditure (EEE) relative to FFM or lean body mass: $EA \text{ (kcal/kg FFM/day)} = (EI \text{ (kcal/day)} - EEE \text{ (kcal/day)})$. The measurement of each of these components requires expertise and is generally imprecise. EI can be assessed by retrospective (recall) or prospective (written or electronic food diary) methods.⁸⁶ EEE is usually assessed by an exercise log and tables of energy expenditure associated with sports/exercise activities, but may be supplemented where available by data collected via modern sports technology (eg, Global Positioning System Units, Heart Rate Monitors or Power Meters). Ideally, EI and EEE are measured over a similar time period that is representative of habitual practices. FFM can be quantified by methods such as dual-energy X-ray absorptiometry (DXA) and anthropometry.⁸⁷ A measurement of resting metabolic rate via indirect calorimetry may provide confirmation of suppressed metabolism secondary to low EA. Underpinning factors related to an unintentional mismatch between EI and large training/competition volume, intensity or misguided weight loss practices may be relatively easy to diagnose.

The Brief Eating Disorder in Athletes Questionnaire (BEDA-Q) is a validated screening tool that shows promising results in terms of distinguishing between female elite athletes

with and without ED/DE.⁸⁸ The Gold Standard for the diagnosis of EDs is the Eating Disorder Examination interview (EDE-16).⁸⁹ For diagnostic criteria for ED see APA.¹⁶

Menstrual dysfunction

FHA is a diagnosis of exclusion. Assessment of irregular menses should include a menstrual history assessing age of menarche, regularity of menses, use of medications, the presence of other health issues and a family menstrual history. Physical examination includes assessment of anthropometry, pubertal stage, signs of ED and secondary causes of amenorrhoea.⁸³ Pelvic examination may reveal pregnancy or hypoestrogen-related vaginal atrophy. Laboratory assessment of haemoglobin, luteinising hormone, follicle stimulating hormone, prolactin, oestradiol, T4, thyroid stimulating hormone, pregnancy and androgen profile may be indicated. More extensive testing might include a pelvic ultrasound and endometrial sampling to rule out other gynaecological pathologies.

Bone health

In athletes with low EA, DE, ED or amenorrhoea of over 6 months, BMD should be measured by DXA.^{90 91} In the adolescent, DXA should include the whole body (head excluded) in addition to the lumbar spine.^{6 92} As athletes in weight-bearing sports should have 5–15% higher BMD than non-athletes^{93 94} a BMD Z-score <−1.0 SD warrants further attention. In the athlete population, low BMD is defined as a Z-score between −1.0 and −2.0 SD, together with a history of nutritional deficiencies, hypoestrogenism, stress fracture or other secondary clinical risk factors for fracture. A value below −2.0 SD is considered as osteoporosis with the presence of secondary clinical risk factors.⁶ The recommended interval to reassess BMD via DXA scan for athletes at risk, or who are being treated for low BMD is 12 months in adults and a minimum of 6 months in adolescents.⁹⁵

Treatment strategies of RED-S

Treatment strategies for low EA

The treatment of low EA should involve an increase in EI, reduction in exercise or a combination of both. The only strategy to have received scientific scrutiny is the addition of an energy-rich supplement (eg, liquid meal product) to habitual intake and a small reduction in, or introduction of a rest day to the weekly training programme.^{96–98} Despite the small sample size, this intervention was successful,^{96 97} however, not in all studies⁹⁸ as this strategy may fail to address many underlying dietary and psychological factors. While developing a strategy to implement a diet of known and appropriate EA may be logical, it is usually impractical due to the challenges of measuring EA in the field. Therefore, a practical treatment approach to address low EA is to implement an eating plan that increases current EI by ~300–600 kcal/day (1.2–2.4 MJ/day) and addresses suboptimal practices related to energy spread over the day and around exercise sessions, dietary composition and food-related stress.

Treatment strategies for low EA-associated menstrual dysfunction

In collegiate athletes, weight gain is the strongest predictor of recovery of normal menstrual function.^{99–101} Adequate protein and carbohydrate intake is recommended to restore liver glycogen to facilitate LH pulsatility.^{31 102} The time frame for the resumption of menses varies according to the severity of the energy deficiency and the duration of the menstrual dysfunction.¹⁰⁰

Although oral contraceptives (OCs) may be considered for athletes requiring contraception,¹⁰³ these may mask the low EA,

menstrual dysfunction and perpetuate bone loss. Injectable depot medroxyprogesterone, another form of contraception, can cause amenorrhoea and hence prolonged use can adversely affect BMD,¹⁰⁴ and adolescent bone mass accrual,¹⁰⁵ which is reversible to a certain extent on discontinuation.¹⁰⁶ Many physicians prescribe low-dose OCs as hormone replacement in the amenorrhoeic athlete, however, this intervention does not correct the aetiological cause of relative energy deficiency and may compromise the attainment of peak bone density.¹⁰⁷

Treatment options to restore fertility may include increasing EA. Pharmacological agents may be necessary to stimulate ovulation in luteal phase deficiency.²⁷ Attention must be paid to infertility treatments identified in the WADA Prohibited List.⁵⁸

Treatment strategies to optimise bone health

Strategies to reverse bone loss in women with FHA parallel those used for amenorrhoeic women with anorexia.¹⁰⁸ In the latter population, weight gain with or without the subsequent resumption of menses restores the coupling of bone formation and resorption^{109–110} and improves BMD.¹⁰⁹ However, full recovery may not be feasible, as bone microarchitecture is also impaired.¹¹¹ EI alone increases bone mass by 1–10% in women with anorexia.^{110–112} It is essential to restore the energy and oestrogen-dependent mechanisms of bone loss in order to improve mineralisation of trabecular bone and growth of cortical bone.⁴¹ Mechanical loading and high-impact sports are known to positively affect BMD^{113–114} as well as bone geometry.^{115–116} Programmes of high-impact loading and resistance training should be implemented at least 2–3 days/week for athletes in non-weight bearing sports and/or those with decreased BMD.⁶

The athlete diet should include 1500 mg/day of calcium through dietary sources with supplementation if required.¹¹⁷ The Endocrine Society Guideline (2011) recommends maintaining vitamin D [25(OH)D] blood levels above 32–50 ng/mL, with 1500–2000 IU/day of vitamin D.^{118–119} Vitamin D deficiency is common in northern latitudes, especially during winter when there are fewer hours of sunlight and among athletes who train indoors.^{120–121} Other factors include dark pigmented skin, and the use of sunscreen. A recent meta-analysis of vitamin D

supplementation found a positive effect in femoral and hip BMD, with no effect in the spine.¹²²

Transdermal oestradiol (given with cyclic progesterone) has shown some success in increasing BMD in patients with anorexia.¹²³ In some studies, combination OCs containing 20–35 µg of oestradiol have maintained or improved BMD in amenorrhoeic athletes.^{124–125} However, use of the OCP in athletes with FHA have been reported to have a detrimental effect on BMD through the suppression of androgen secretion and cause premature closure of the epiphyses compromising growth of the long bones in adolescents.¹²⁶

Bisphosphonates, which inhibit the resorption of bone, are not recommended for women of reproductive age, as they are stored in bone for prolonged amounts of time and have been shown to be teratogenic.^{127–128} Other therapies including raloxifene (a selective oestrogen receptor modulator or SERM), parathyroid hormone peptides, teriperatide and calcitonin, are also not approved for use in premenopausal women. Some novel potential therapies are being developed, but clinical trials are lacking.^{129–130} These include insulin-derived growth factor (a bone anabolic agent)^{131–132} and leptin which can be used to stimulate appetite, thus effecting resumption of menses and subsequent improvement in BMD.^{133–135}

In men, detection and correction of any underlying pathology is essential, including testosterone therapy with hypogonadism and osteoporosis. Bisphosphonates may be used as monotherapy, as consolidative therapy after a course of teriperatide administration or in combination with hormonal replacement.¹³⁶ Denosomab and strontium ranelate also increase BMD in men with osteoporosis.¹³⁷

Treatment strategies for psychological sequelae

If an athlete will not or cannot follow the treatment plan, a psychological factor is generally present. Athlete resistance to treatment usually increases with the severity of the eating problem.¹³⁸ Treatment should be provided by a mental health professional knowledgeable about the management of EDs in athletes. The frequency, types, intensity and duration of psychological treatment depend on the severity, chronicity and the medical and psychological complications of the eating problem,

Table 1 Relative Energy Deficiency in Sport risk assessment model for sport participation (modified from Skårderud *et al*)¹⁴⁰

High risk: no start red light	Moderate risk: caution yellow light	Low risk: green light
<ul style="list-style-type: none"> ▶ Anorexia nervosa and other serious eating disorders ▶ Other serious medical (psychological and physiological) conditions related to low energy availability ▶ Extreme weight loss techniques leading to dehydration induced haemodynamic instability and other life-threatening conditions 	<ul style="list-style-type: none"> ▶ Prolonged abnormally low % body fat measured by DXA or anthropometry using The International Society for the Advancement of Kinanthropometry ISAK¹⁴¹ or non-ISAK approaches¹⁴² ▶ Substantial weight loss (5–10% body mass in 1 month) ▶ Attenuation of expected growth and development in adolescent athlete ▶ Abnormal menstrual cycle: FHA amenorrhoea >6 months ▶ Menarche >16 years ▶ Abnormal hormonal profile in men ▶ Reduced BMD (either from last measurement or Z-score < -1 SD). ▶ History of 1 or more stress fractures associated with hormonal/menstrual dysfunction and/or low EA ▶ Athletes with physical/psychological complications related to low EA/ disordered eating - ECG abnormalities- Laboratory abnormalities ▶ Prolonged relative energy deficiency ▶ Disordered eating behaviour negatively affecting other team members ▶ Lack of progress in treatment and/or non-compliance 	<ul style="list-style-type: none"> ▶ Healthy eating habits with appropriate energy availability ▶ Normal hormonal and metabolic function ▶ Healthy BMD as expected for sport, age and ethnicity ▶ Healthy musculoskeletal system

BMD, bone mineral density; DXA, dual-energy X-ray absorptiometry; EA, energy availability; FHA, functional hypothalamic amenorrhoea; ISAK, International Society for the Advancement of Kinanthropometry

Table 2 The Relative Energy Deficiency in Sport Decision-based Return-to-Play Model (modified from Creighton *et al*¹⁴³)

Steps	Risk modifiers	Criteria	Red-S-specific criteria
Step 1 Evaluation of health status	Medical factors	Patient demographics Symptoms Medical history Signs Laboratory tests Psychological health Potential seriousness	Age, sex (see Yellow light column of table 1) Recurrent dieting, menstrual health, bone health Weight loss/fluctuations, weakness Hormones, electrolytes, ECG and DXA Depression, anxiety, disordered eating/eating disorder Abnormal hormonal and metabolic function Stress fracture
Step 2 Evaluation of participation risk	Sport risk modifiers	Type of sport Position played Competitive level	Weight sensitive, leanness sport Individual vs team sport Elite vs Re-creational
Step 3 Decision modification	Decision modifiers	Timing and season Pressure from athlete External pressure Conflict of interest Fear of litigation	In/out of season, travel, environmental factors Desire to compete Coach, team owner, athlete family and sponsors If restricted from competition

DXA, dual-energy X-ray absorptiometry.

as well as the comorbid psychological disorders that often accompany such problems. Ideally, eating problems can be treated on an outpatient basis. Medical complications, risk of self-harm and lack of progress in outpatient treatment indicate a need for more intensive treatment regimens including inpatient, residential, partial hospitalisation and intensive outpatient programmes. Treatment is usually required for several months. Treatment modalities might include cognitive behavioural therapy, dialectical behaviour therapy or family-based therapy. Comorbid conditions, such as depression, anxiety and other psychological problems also need to be addressed. Pharmacotherapy may also be recommended; antidepressants are the class of medications most often prescribed.¹³⁹

Clinical models for sport participation and return-to-play

Risk assessment for sport participation

There are limited evidence-based guidelines to assist the athlete healthcare team in the assessment for sport participation clearance with RED-S. Based on the guidelines from the Norwegian Olympic Training Center¹⁴⁰ and the collective expertise of the IOC Consensus group, a new model of criteria to assess risk for sport participation has been developed (table 1). This model can be incorporated into the PHE. The criteria for this model are based on those used at the Norwegian Olympic Training Center,¹⁴⁰ and also recommended by the IOC Body Composition, Health and Performance Working group.⁸

It is recommended that athletes in the ‘High Risk—Red Light’ risk category should not be cleared to participate in sport. Owing to the severity of their clinical presentation, sport participation may pose serious jeopardy to their health and may also distract the athlete from devoting the attention needed for treatment and recovery.¹³⁸ These athletes should receive treatment using a written treatment contract (see online

supplementary appendix 1). Athletes in the ‘Moderate Risk—Yellow Light’ risk category should be cleared for sport participation only with supervised participation and a medical treatment plan. Re-evaluation of the athlete’s risk assessment should occur at regular intervals of 1–3 months depending on the clinical scenario to assess compliance and to detect changes in clinical status.

Return-to-play

Decision-making regarding return-to-play (RTP) following time away from sport for recovery from injury and/or illness is based on the assessment of the athlete’s health and the requirements of his/her sport.^{143 144} Table 3 adapts Creightons’s RTP Model and the guidelines from the Norwegian group¹⁴⁰ to the athlete with RED-S through the addition of RED-S specific criteria.

The RED-S Risk Assessment Model is adapted to aid clinicians’ decision-making for determining an athlete’s readiness to return to sport. Following clinical reassessment utilising the three-step evaluation outlined in table 2, athletes can be reclassified into the ‘High Risk—Red Light’, ‘Moderate Risk—Yellow Light’ or ‘Low Risk—Green Light’ categories. The RED-S return-to-play model (table 3) outlines the sport activity recommended for each risk category.

Recommendations to address RED-S

The following recommendations are formulated based on a review of the scientific evidence and the collective expertise of the IOC Consensus group relating to the RED-S.

Athlete entourage recommendations

The athlete’s entourage can prevent RED-S through implementation of the following strategies:

Table 3 The Relative Energy Deficiency in Sport Return-to-Play Model (modified from Skårderud *et al*, 2012)¹⁴⁰

High risk red light	Moderate risk yellow light	Low risk: green light
<ul style="list-style-type: none"> ▶ No competition ▶ Supervised training allowed when medically cleared for adapted training ▶ Use of written contract (see supplementary appendix 1) 	<ul style="list-style-type: none"> ▶ May compete once medically cleared under supervision ▶ May train as long as is following the treatment plan 	<ul style="list-style-type: none"> ▶ Full sport participation

- ▶ Educational programmes on RED-S, healthy eating, nutrition, EA, the risks of dieting and how these affect health and performance.
- ▶ Reduction of emphasis on weight, emphasising nutrition and health as a means to enhance performance.
- ▶ Development of realistic and health-promoting goals related to weight and body composition.
- ▶ Avoidance of critical comments about an athlete's body shape/weight.
- ▶ Use of reputable sources of information.
- ▶ Promotion of awareness that good performance does not always mean the athlete is healthy.
- ▶ Encouragement and support of appropriate, timely and effective treatment.

Healthcare professional recommendations

HealthCare professionals can decrease the health implications of RED-S through the following interventions:

- ▶ Identification of a multidisciplinary athlete health support team including sports physician, nutritionist, psychologist, physiotherapist and physiologist.
- ▶ Education of the medical team in the detection and treatment of the RED-S.
- ▶ Implementation of the RED-S Risk Assessment Model in the PHE and the RED-S RTP Model.

Sport organisation recommendations

Sport organisations such as International Federations, National Olympic Committees and National Sport Federations can prevent RED-S through the implementation of:

- ▶ Preventative educational programmes;
- ▶ Rule modifications/changes to address weight-sensitive issues in sport;
- ▶ Policies for coaches on the healthy practice of managing athlete eating behaviour, weight and body composition.

Research recommendations

Research institutions should focus on research and evaluation of:

- ▶ The aetiology and treatment of athletes with RED-S including males, ethnic and disabled populations;
- ▶ Design and validation of tools to accurately measure EA in the clinical setting;
- ▶ The validation of screening tools and treatment programmes such as the RED-S Risk Assessment Model and RED-S RTP Model.

What is already known on this topic?

- ▶ The International Olympic Committee (IOC) has published a Consensus Statement and Position Stand (2005) on the Female Athlete Triad outlining the pathophysiology and prevalence of this syndrome.
- ▶ Low energy availability is the aetiological process underpinning the development of the Female Athlete Triad.
- ▶ Prevalence measures of the Triad indicate that female athletes are particularly vulnerable to this syndrome in sports where leanness and/or weight are important due to their role in performance, appearance or requirement to meet a competition weight category.

How might this IOC consensus statement impact on clinical practice in the near future?

- ▶ Scientific evidence and clinical experience around the effects of low energy availability shows that several body systems in addition to the reproductive and musculoskeletal systems are affected, and that men are at risk as well as women.
- ▶ Based on the evidence, a broader term, which includes what has so far been called the 'Female Athlete Triad', is introduced: Relative Energy Deficiency in Sport (RED-S).
- ▶ Owing to the potential serious health consequences of this syndrome, there is a need in the clinical realm to establish a 'Sport Risk Assessment' model to protect the health and well-being of athletes with this syndrome.
- ▶ 'Return-to-Play' guidelines will assist the athlete health support team in the safe return of the affected athlete to sport participation.
- ▶ Recommendations for sport organisations, athlete entourage and research institutions will result in future awareness, understanding and further evidence-based knowledge of the RED-S.

Acknowledgements The authors would like to acknowledge the work of Barbara Drinkwater in the field of the Female Athlete Triad, and for her ongoing support of the advancement of science in this domain.

Contributors MM and JS-B were involved in the substantial contributions to conception and design, co-coordinator of IOC Expert Group + Consensus meeting, drafting and revising the manuscript and final version to be published. LB, SC NC, CL, NM and RS, were the members of IOC Expert Group, contribution at Consensus meeting, substantial contribution to drafting and final revision of the manuscript to be published. KS was the contributor at Consensus meeting, final revision of the manuscript to be published. RB was the Director IOC Medical & Scientific Department, participant at Consensus meeting, final revision of the manuscript to be published. AL was the Chairman of IOC Medical Commission, participant at Consensus meeting, final revision of the manuscript to be published.

Funding The Consensus meeting was funded by the International Olympic Committee.

Competing interests None.

Provenance and peer review Commissioned; internally peer reviewed.
