Dimension of Inequality - Work and Health - Practical session

PART A:

In paper from 1998, Bosma et al looked at the role of job control and effort-reward imbalance on incidence of coronary heart disease in Whitehall II study. Please see results summarised in following two pictures:

What would you say about the role of two measures of work stress and its role in developing CHD in this population? Why do you think that researchers used adjusting strategy as shown in the figures?

PART C: Job strain as a risk-factor for CHD: a collaborative meta-analysis of individual participant data (Kivimaki et al, 2012)

Summa

Background Published work assessing psychosocial stress (job strain) as a risk factor for coronary heart disease is inconsistent and subject to publication bias and reverse causation bias. We analysed the relation between job strain and coronary heart disease with a meta-analysis of published and unpublished studies.

Methods We used individual records from 13 European cohort studies (1985–2006) of men and women without coronary heart disease who were employed at time of baseline assessment. We measured job strain with questions from validated job-content and demand-control questionnaires. We extracted data in two stages such that acquisition and harmonisation of job strain measure and covariables occurred before linkage to records for coronary heart disease. We defined incident coronary heart disease as the first non-fatal myocardial infarction or coronary death.

Findings 30 214 (15%) of 197 473 participants reported job strain. In 1·49 million person-years at risk (mean follow-up 7·5 years [SD 1·7]), we recorded 2358 events of incident coronary heart disease. After adjustment for sex and age, the hazard ratio for job strain versus no job strain was 1·23 (95% CI 1·10-1·37). This effect estimate was higher in published (1·43, 1·15-1·77) than unpublished (1·16, 1·02-1·32) studies. Hazard ratios were likewise raised in analyses addressing reverse causality by exclusion of events of coronary heart disease that occurred in the first 3 years (1·31, 1·15-1·48) and 5 years (1·30, 1·13-1·50) of follow-up. We noted an association between job strain and coronary heart disease for sex, age groups, socioeconomic strata, and region, and after adjustments for socioeconomic status, and lifestyle and conventional risk factors. The population attributable risk for job strain was 3·4%.

Interpretation Our findings suggest that prevention of workplace stress might decrease disease incidence; however, this strategy would have a much smaller effect than would tackling of standard risk factors, such as smoking.

Table: Characteristics of eligible participants	tics of eligible pa	rticipants						

Please read the abstract and look at the descriptive table. Summarize main findings of the study on the basis of the abstract.

Please look at the table on the left side of next page. On the basis of the results shown there do you still believe all the results presented in the abstract being valid summary of findings?

Look at remaining two figures. Why did authors display such figures? Please explain.

The findings of this paper were widely discussed and some researchers were quite critical. What do you think was the main criticism of this paper?
