Abstract

In Humanities and Social Sciences, a two-tier journal classification implemented by selected scientific experts has been recently used in Italy in the context of the National Habilitation programme; for the same period, peer review is available for a large number of journal articles, developed in the framework of two national evaluation exercises (VQR 2004-2010 and VQR 2011-14). We take advantage of this rich dataset in order to check if journals classified as top class by scientific experts show higher impact and if articles published in those journals receive higher marks in peer-reviewed evaluation exercises. Results are rather mixed: the impact indicator does not seem to be significantly higher for top-class journals with respect to those classified in the second tier; on the other hand, median marks received by individual articles in the two evaluation exercises are significantly higher for top journals. We can draw two main conclusions from the analysis: the first is that journal classification performed by experts does not necessarily rely on impact measures, depending more instead on different criteria for journal selection. However, journal classification based on experts' judgement seem to proxy quite well on average the quality of individual articles as measured by peer review.

Introduction

Peer review is generally considered as the best method for evaluating research (Moed, 2008); however, it can be costly and time consuming, and may be affected by various kind of biases (Lee et al, 2013). For these reasons, some countries use ratings or rankings of journals as a way to inform peer evaluation (see for instance Walker et al, 2018). Ratings may be either based on indicators or on experts' opinions: typically, indicators are widely used in Science, Technology, Engineering and Mathematical (STEM) areas, whilst experts judgements are mostly used in Humanities and Social Sciences (SSH[1]). In Italy, journal indicators have been used in STEM areas in the country' two main evaluation exercises, the VQR 2004-2010 and VQR 2011-14 (see Anfossi et al, 2016); in SSH, instead, peer review was not supported by external information concerning journal classification, even if reviewers had the knowledge of the venue in which the article under evaluation was published[2]. However, in those areas journal ratings have been used in the context of the procedures concerning the National Habilitation of candidates for professorships. The co-existence in the same county and for the same period of time of two distinct evaluation procedures, one based on pure peer review of journal articles and the other on journal classification, makes it possible to test the robustness of experts' journal classification: this may be done contrasting journal ratings with the results obtained on the basis of the peer review of individual articles (Bonaccorsi et al., 2018). Moreover, robustness of classification may also be tested against the information concerning impact indicators of journals extracted from the Scopus database. In the following, we firstly describe with some detail the journals database used by ANVUR in the National Habilitation procedures. We hence present the results of the comparison among peer review at the article

[1] For a more complete discussion on the various methods of journal rating and ranking, see Ferrara and Bonaccorsi (2016).
[2] For a description of the Italian evaluation exercise, see Ancaiani et al (2015).

and journal level and among journal peer review and the indicators extracted from Scopus. Some consideration on the results obtained concludes the paper.

The classification of journals for the National Habilitation Programme

According to Ministerial Decree 76/2012, updated with the Ministerial Decree 120/2016, in SSH candidates for professorship are selected on the basis of various indicators of research activity, including the number of articles in scientific journals and in A-Class journals. According to the decrees, ANVUR is in charge of producing the two-tier classification of scientific and A-Class journals, with the possible assistance of external scientific experts. ANVUR has issued a regulation establishing the formal requirements for a journal to be classified as "scientific" or "A-Class" (see ANVUR, 2017a). More precisely, journals should possess specific process and product requirements. As for process requirements, a scientific journal should target an academic audience, possess a ISSN code and employ at least a single-blind method of peer review. On top of that, A-Class journals should employ a double-blind method of peer review; moreover, for A-Class journals, articles that have been submitted for evaluation in the VQR should have received on average a better evaluation than that received by scientific journals in the same scientific sector. As product requirements, journals should comply with pre-defined rules in terms of regularity of publication, Board composition, diffusion in the scientific community, rules of access, scientific content and international scope. According to ANVUR rules, journals in Economics and Statistics should also have to comply with pre-determined requirements in terms of impact, as measured by journal indicators extracted from international databases. Currently, a group of 42 experts specifically appointed by ANVUR on the basis of a public call is in charge of verifying the aforementioned requirements (see http://www.anvur.it/gruppo-di-lavoro-ric/gruppo-di-lavoro-riviste-e-libri-scientifici-2017/ for the list of experts). Overall, a total of over 20,000 and 5,500 journals are classified as scientific and A-Class, respectively, with the sectoral distribution shown in table 1.

Table 1. Rated journals by ANVUR (number of Scientific and Class A journals)

Areas	*N. of Scientific*	*N. of A-Class*	*% of A-Class*
Architecture	2,115	305	12.6%
Antiquities, philology, literary studies, art history	6,488	1,992	23.5%
History, philosophy and pedagogy	6,873	1,420	17.1%
Law	2,330	422	15.3%
Economics and Statistics	7,150	1,031	12.6%
Political and social science	3,988	1,059	21.0%
Total	**20,016**	**5,476**	**21.5%**

Source: Authors elaboration on ANVUR data

Figure 1 presents the world distribution of scientific journals classified by ANVUR (information on publisher's country is available for 70% of journals): most of the journals are concentrated in Europe and the US, with a good representation also for journal edited in Australia, Brazil, Canada and India; despite the strong growth in scientific publishing in the last decade, China is still under represented in the Italian classification, together with the rest of Asia, the Latin America and Africa.

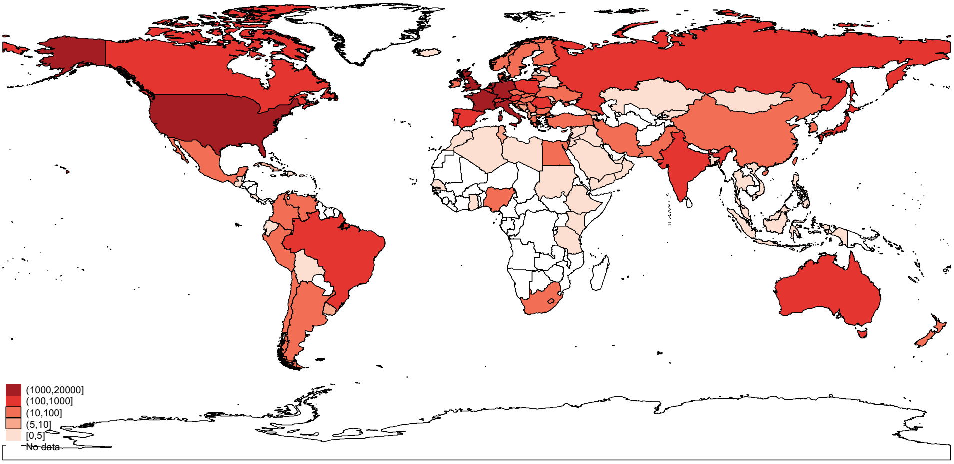

Figure 1. World distribution of journals rated by ANVUR

Source: Authors elaboration on ANVUR data

As for the language of publication, almost 50% of the classified journals are published in English and 14% in Italian (see table 2). There is also a remarkable share of journals that are published in more than one language, while a small but not negligible share of publications is issued in various other languages.

Table 2. Language of classified journals

Language	*Frequency*	*Percentage*	*Cumulate percentage*
English	9,816	49,04	49,04
Multilanguage	3,384	16,91	65,95
Italian	**2,847**	**14,22**	**80,17**
French	1,011	5,05	85,22
Spanish	774	3,87	89,09

Journal classification and Scopus indexation

ANVUR classification, with the only aforementioned exception of the classification in Economics and Statistics, is not influenced by standard bibliometric indicators such as the impact factor. However, it is possible to evaluate ex post whether classified journals are indexed in the major international journal databases, and if the frequency of classification is higher for A-Class with respect to scientific journals: indeed, if this is the case, the evidence may be considered as a very preliminary confirmation of the robustness of the ANVUR classification, also helping shedding some light on the influence of impact indicators on journal classification. In this respect, table 3 reports the share of classified journals that are indexed in the Scopus[3] database, distinguished by scientific area; on average, 43% of scientific journals and over 63% of top rated journals are also indexed in Scopus. However, percentages differ remarkably among areas: in Economics, over 61% of scientific journals and almost 96% of A-Class journals are included in the Scopus database, while on the other hand in Law only 20.3% of scientific journals and 27% of A-Class journals are indexed. Similar results are obtained by Siversten (2014) on Norway's higher education institutions.

Table 3. Classified journals indexed in Scopus

Areas	*N. of Scientific*	*N. of Scopus*	*% Scopus*	*N. A-Class*	*N. Scopus A*	*% Scopus A*
8 - Architecture	2,115	742	35.1%	305	188	61.6%
10 - Antiquities, philology, literary studies, art history	6,488	1,945	30.0%	1,992	925	46.4%
11 - History, philosophy and pedagogy	6,873	2,912	42.4%	1,420	1012	71.3%
12 - Law	2,330	473	20.3%	422	114	27.0%
13 - Economics and Statistics	7,150	4,369	61.1%	1,031	989	95.9%
14 - Political and social science	3,988	1,892	47.4%	1,059	869	82.1%

Source: Authors elaboration on ANVUR and Scopus data

Journals classified by ANVUR pertain to a large number of Scopus ASJCs': in this respect, table 4 shows the list of the Scopus subject categories including at least 100 journals classified by ANVUR. ASJC are ordered with respect to the number of journals included in the ANVUR classification; the table also reports the number of journals for each ASJC and for each ANVUR scientific Area (see also table 3 for the area definition). Overall, most common ASJCs' are those that are more specific to Humanities and Social Sciences: for instance, 780 journals classified by ANVUR are indexed in the ASJC "Sociology and Political Science" and 735 in "History". However, a non-negligible 426 and 258 journals respectively are indexed in "Medicine (All)" and "Applied Mathematics", respectively, an indication that Italian SSH scholars tend also to publish outside of their more obvious fields of interest.

Table 4. Mapping of asjc covered by ANVUR classification, by Area (only asjc with over 100 journals are reported)

Asjc	*Denominaton asjc*	*8*	*10*	*11*	*12*	*13*	*14*	*Total*
3312	Sociology and Political Science	22	127	159	52	169	251	780
1202	History	59	341	254	14	21	46	735
2002	Economics and Econometrics	17	9	52	23	461	10	572

[3] Scopus has a larger coverage for journals classified by ANVUR with respect to possible alternatives; this result is in line with the literature (see for instance Siversten, 2014) which shows that the coverage of humanities and social sciences is larger in Scopus than in other databases.

Journal classification and the Italian research evaluation exercise

As a next step in our analysis, we check for the use of classified journals in the two main Italian evaluation exercises: table 5 shows the number of scientific journals classified by

ANVUR for which at least 1 article was submitted for evaluation in the VQR 2004-2010 and VQR 2011-14. As it may be seen, the share of journals used in the two evaluation exercises with respect to the total of Scientific journals was on average equal to 23.4% in the first VQR, dropping to 21.1% in the second exercise. Indeed, the fall of the share of classified journals used in the second VQR is a direct result of the fact that the second exercise covered a shorter time span (4 years instead of 7); as consequence, in the second exercise each Italian researcher was asked to submit only two publications instead of three. The share of journals with at least one article evaluated in the two VQRs' reaches 38.5 and 34.9% respectively in the two evaluation exercises in Law, while it is equal to only 27.4% and 24.9% respectively in History, philosophy and pedagogy. Journal articles are a more common media to disseminate knowledge in Law than in History and Philosophy: in the second VQR exercise, the share of journal articles on the total number of publications submitted for evaluation was in fact equal to 39.6% in Law and to 34.9% in History and Philosophy. In this respect, however, Economics and statistics was the area with the highest share of articles with respect to total submissions (72.8%), followed by Political and Social Sciences (40.9%); in Antiquities and literary studies the share was equal to 32.3%, in Architecture to 26.4%[4].

Table 5. Journals classified by ANVUR whose scientific articles was submitted to VQR 2004-2010 and VQR 2011-2014

Areas	*N. of Scientific journals*	*VQR 2004-2010*	*% VQR 2004-2010*	*VQR 2011-2014*	*% VQR 2011-2014*

A test for robustness of Journal classification

In the previous sessions, we have provided first evidence that the share of indexed Journals is larger for A-Class than for merely scientific journals. This result may be considered as a very preliminary evidence that the ANVUR two-tier classification is robust with respect to the probability for a journal of being indexed in Scopus, which in turn can be considered as a proxy for journal quality. However, it may also be the case that the inclusion in Scopus can have a positive influence on journal classification: in fact, according to the ANVUR requirements, indexation is considered as an explicit criteria of classification in economics and statistics, but we cannot exclude that it may have been used as a reference also in other disciplines. In order to dig deeper into the relationship among ANVUR classification and journal indexation, for every academic discipline (in Italy called "Settore Concorsuale") in which candidates for professorship are selected[6] we compute the mean of the SJR indicator[7] for the two subsets of scientific journals that are classified as No-A Class[8] and A-Class.

[4] See also ANVUR (2017b), table 2.6

[5] The total percentage of scientific journal submitted in the two VQR is lower than the percentages of six areas, because a large number of journal was classified in more than one area.

[6] The list of academic discipline is available at http://attiministeriali.miur.it/media/265754/allegato_a.pdf

Figure 2 shows the box plot distributions of the SJR indicator in the 78 academic disciplines of interest grouped into six scientific areas. The wideness of the box represents the dispersion among academic disciplines in terms of SJR. In area 8 and 12, experts approved a mutual recognition of A-class evaluations among different academic fields; for this reason, boxplot shows no variance among them.

In general, the median value of SJR is clearly higher for A-Class than for merely scientific journals in Economics and Statistics and, even if only marginally, in Architecture; it should however be remembered that, according to ANVUR rules, in Economics and Statistics impact was one of the criteria to be used for journal classification: hence, the fact that A-Class journals show a higher impact (as measured by the SJR) does not come as a surprise. In other areas, the median value of SJR is instead quite similar for the two categories of journals, being indeed marginally higher for scientific rather than for A-Class journals in Antiquities, philology, literary studies and art history. Overall, there is no clear evidence that A-Class journals are characterised by a higher impact with respect to Scientific journals, at least if impact is measured in terms of the value of the SJR indicator.

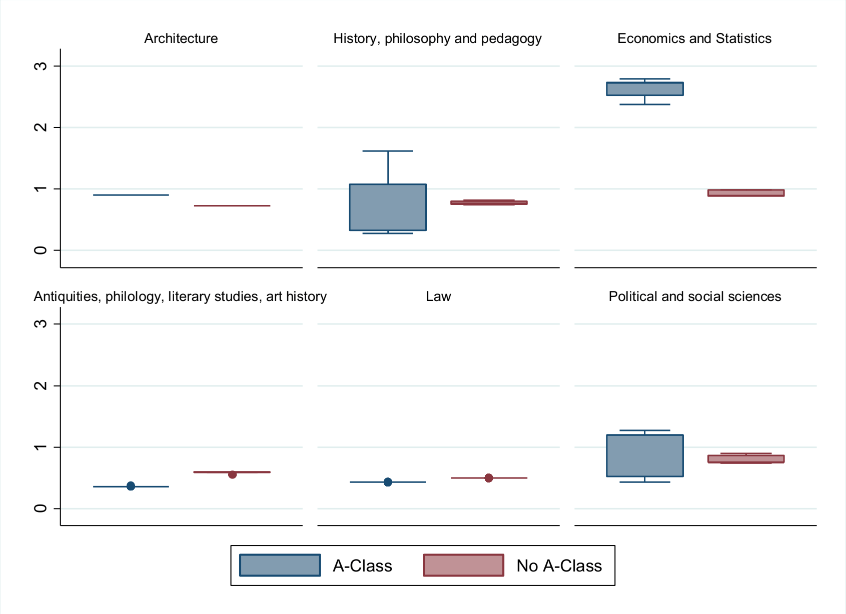

Figure 2. Box plot of SJR (2017) average value of ANVUR journals covered in Scopus in the 78 academic disciplines of interest grouped into six scientific areas

Source: Authors elaboration on ANVUR data

In the two Italian VQRs', articles in SSH were evaluated with peer review. Peer evaluation was coordinated by the 170 members of the disciplinary Groups of Evaluation Experts (GEV

[7] We prefer to use the SJR indicator with respect to possible alternatives like the impact factor or the h index because the SJR allows to take into account the importance or prestige of the journals where citations come from.

[8] The list of scientific journals also includes A-Class journals; in the remaining of the paper, we compare A-Class journals only with the scientific journals that are not also comprised in the A-Class list.

in the Italian acronym) in SSH, assisted by a very large group of national and international reviewers (considering only SSH, 7.263 and 8.343 reviewers were respectively used in the two evaluation exercises). Reviewers were asked to assess the merit of each article against the criteria of originality, methodological rigour and impact: in this sense, VQR evaluation is based on criteria that are quite different from those adopted in the evaluation of journals, as reported in the first section of the paper. The only exception is the area of economics and statistics, were VQR evaluation was explicitly based on journal impact, a parameter that in this area is also used in journal evaluation. The independence of the VQR evaluation with respect to the journal evaluation is also confirmed by the fact that the group of experts in charge of journal classification is only a small subset of the much larger group of VQR GEV and reviewers. Moreover, of the 42 experts forming the group in charge of journal classification, six out of them were also part of the GEVs. However, it should be considered that experts and reviewers had access to the venue of the article they valued, hence we cannot completely rule out that it may have influenced their opinion somehow. Figures 3 and 4 show the box plot distribution of the marks received in the two VQR exercises by the articles published in A-Class and Non-A Class journals. In total, we consider 34.929 articles (19.323 in the VQR 2004-10 and 15606 in the VQR 2011-14). In this case, there is quite a clear evidence, both in the VQR 2004-2010 and in the VQR 2011-14, that the papers published in A-Class journals received an higher mark than those published in no-A Class journals. This appear to be particularly true in Economics and Statistics, but a remarkable difference does emerge also for Architecture, History and Philosophy and Law. Differences tend to be quite similar in the two VQR exercises.

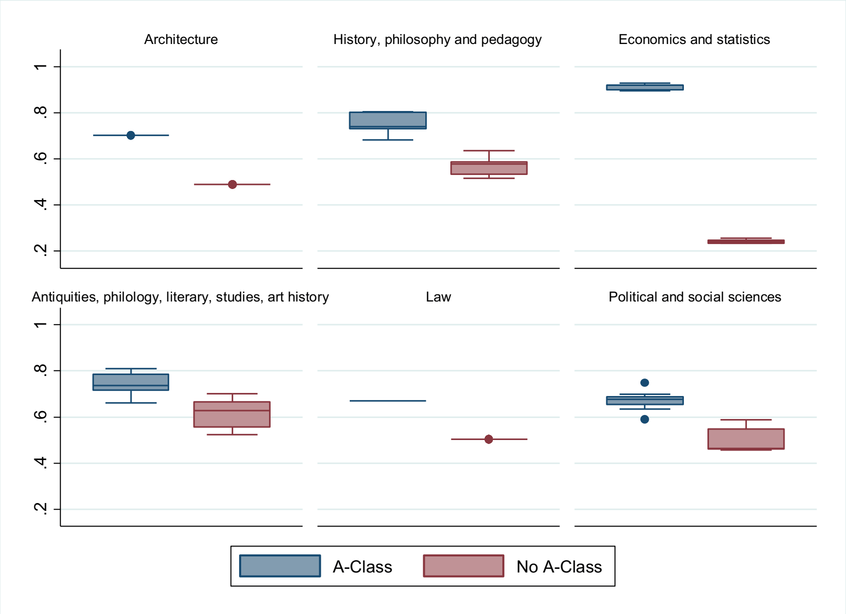

Figure 3. Box plot of VQR average value of ANVUR journals submitted to VQR 2004-2010 in the 78 academic disciplines of interest grouped into six scientific areas

Source: Authors elaboration on ANVUR data

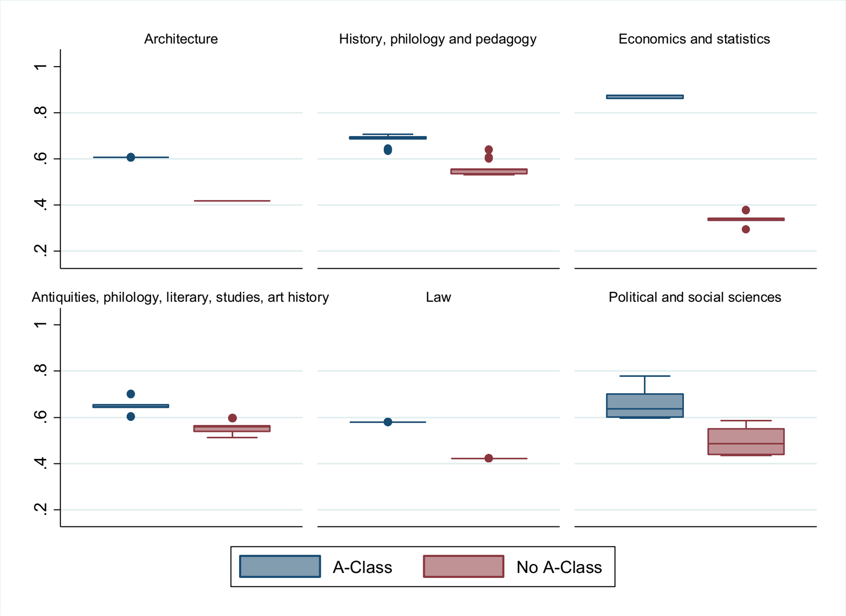

Figure 4. Box plot of VQR average value of ANVUR journals submitted to VQR 2011-2014 in the 78 academic disciplines of interest grouped into six scientific areas

Source: Authors elaboration on ANVUR data

As a final step, we propose a simple test for evaluating the statistical significance of the differences among A-Class and no-A Class journals in terms of the value of the SJR indicator and of the marks received in the two VQR exercises. The null hypothesis is that the score (SJR or VQR) of A-Journals is equal to that of No Class A journals, and this is tested against the one-side alternative that the score is higher than that of No Class A journals:

$$H_1 = A\ rated\ journals\ average\ score > No\ A\ rated\ journals\ average\ score$$

The test is calculated as follows:

$$t_{calculated} = \frac{A\ rated\ journals\ average\ score - No\ A\ rated\ journals\ average\ score}{s_{pooled}\sqrt{\frac{1}{n.of\ A\ rated\ journals} + \frac{1}{n.of\ NO\ A\ rated\ journals}}}$$

Table 6 shows the results: the difference among VQR results for Class A and non Class A journals is almost always statistically significant, for all sectors and Area and for both VQR exercises; the only exceptions are a sector in History and Philosophy and two in Political and Social Sciences. On the other hand, the difference among Class A and non Class A journals in terms of SJR is never statistically significant in Law and in Antiquities, philology, literary studies art and history; mixed results emerge in other areas.

Source: Authors elaboration on ANVUR data

Concluding remarks

Using a large dataset of over 20 thousands journals and 35 thousands articles, we have checked for the robustness of the journal classification performed by ANVUR in the framework of National Habilitation programme with respect to both journal impact (as measured by SJR) and the results of peer evaluation of individual articles, performed by ANVUR in the context of two consecutive national evaluation exercises. First of all, we find that there is no direct relationship among journal classification and journal impact: in other words, experts in charge of journal evaluation (with the only exception of those in the area of Economic and Statistics) does not seem to rely on external information on journals impact to perform their task, rather preferring to base their ratings on other process and product requirements (including, among other things, regularity of publication, Board composition, diffusion in the scientific community, rules of access, scientific content and international scope). The resulting classification, however, seems to offer on average a reliable proxy for the quality of individual articles: indeed, the marks obtained in two independent evaluation exercises by articles published in top tier journals are significantly higher – regardless of the scientific field – with respect to those obtained by articles published in non-top journals. Given the fact that peer evaluation is rather costly and time consuming, the latter result seems to encourage the possibility of using some measure of journal classification in order to support peer review in the context of general systemic research evaluation exercises, even in those disciplines (like Humanities and Social Sciences) where "pure" peer evaluation is usually considered as the only method of choice.

Should I move to diversify my scientific network?
A panel analysis of chemists' careers

Abtract

This study assesses the impact of geographical mobility of academic researchers on the diversification of their co-authorship network, though a bibliometric analysis, at the micro-scale. We selected 80 chemists (CNRS Research Directors and Full Professors) from two French labs: we collected their 9310 publications, in which they collaborated 41628 times with 14783 co-authors. After manually searching for the location of chemists and their co-authors for each publication, we create a database of the 80 personal co-authorship networks, in which each line represents one collaboration between the researcher and one co-author. To analyze the formation and dynamics of these networks over time and the geographic mobility of researchers, we adopted a panel approach to take into account generations and career stages. Results suggest that the social and geographical patterns of scientific network is not so dependent on the mobility of researchers. We point the stability of the volume of new co-authors and of the researcher's lab colleagues per article (whatever generations and career stages). Mobility has only an instant effect on network openness and restricted to the new city attended; it also weakens the interpersonal relations from previous attended cities.

Introduction

A literature interested in the geography of science (Livingstone, 1995; Eckert and Baron, 2013) has been developed in recent years to better understand the spatial distribution of scientific activities. A crucial issue deals with the question of scientists and inventors' mobility, that is considered as essential for knowledge diffusion and widely encouraged by public authorities, especially in the European Union, through various mobility programs (Morano-Foadi, 2005).

Behind the mobility-knowledge diffusion relationship, the underlying hypothesis is that knowledge is attached to individuals (Cañibano, 2006) and it therefore travels along with people who master it. In this context, it is logically assumed that by being mobile, researchers will meet and collaborate with new researchers with whom they will exchange knowledge. This scientific network diversification driven by mobility, would be therefore the indispensable ingredient for production of new knowledge and its circulation across space. In this article, we propose to question this thesis and to answer the following question: should researchers move to diversify their network? Network diversification could be understood in terms of persons/skills (new partners) and in terms of geography (new cities).

Moving in this direction suggests studying the formation and dynamics of personal scientific networks of researchers and identifying the contribution of researchers' geographical mobility to this dynamic. Whereas scientific network dynamics is largely studied in the framework of geography of science into a macro level perspective (most often at the level of cities and countries), it is rarely considered at the micro level of individual careers. Authors have mainly focused on the problem of "brain drain", from Bhagwati (1976) to Breschi *et al*. (2017): the question of mobility has been addressed through the analysis of migratory flows between territories, and nodes in networks are no longer individuals but organizations, cities or countries. In parallel, some research has developed with a greater focus on individuals, testing mainly the impact of researchers' mobility on their performance (Hoisl, 2007; Lawson and Shibayama, 2015). More marginally, some authors have sought to account for the link between mobility and scientific network. Fontes (2012), based on the study of doctoral students' trajectories, shows that international mobility during the PhD thesis enriches the researcher knowledge network. Woolley *et al.* (2009) verifies this result for the post-doctoral mobility of Asian researchers, while Melin (2004, 2005) nuances it ("the dark side of mobility") through the study of Swedish researchers' mobility. Our research is in line with these latter questions. We seek to test the role of mobility in building and developing the scientific network by focusing at a micro level; however, we consider that mobility cannot be studied in isolation. It seems crucial to reintegrate mobility' impact in the context of the ongoing career of the researchers. To explain the scientific network diversification, we therefore question the impact of career dynamics, including mobility.

Empirically, we focus on scientific publications of researchers since it constitutes a relevant indicator of successful collaborations even if they do not capture all researchers' collaborations. Such bibliometric data generally gives reliable information on institutional (laboratory) scale, however those related to the individual scale of researchers remain problematical. Aware of these limits, we use precise data at the individual level from a cohort of eighty chemists located in two French labs. To refine the bibliometric data, we notably have collected the affiliation and the location of each co-author to understand the geography of co-authorship. Thus, we can analyze the formation and dynamics of co-authorship personal network over time. Under which conditions do they diversify their co-authorship, or do they tend to renew collaborations? To what extent is the geography of co-authorship sensitive to the spatial trajectories of chemists? Are scientific collaborations maintained (or not) over time despite geographical distance?

We focus on chemistry, since the co-authorship in this field is particularly dense due to the way research is practiced (experimental dimension, need for technical skills, importance of teams, etc.). Even so, it is not a scientific field in which the average number of co-authors (between 4 and 5) is tremendous. The eighty studied chemists have published around 10000 articles with 15000 co-authors since the beginning of their career. The paper is structured as follows. The next section describes the data, gives descriptive statistics, and present the methodology used to assess the mobility impact on the co-authorship dynamics. The empirical results are commented on in the fourth section. The final section summarizes the main findings and draws some conclusions.

Data and Method

In order to resolve the literature issues identified in the previous part, we choose to grasp the researcher career of 80 chemists and their scientific collaborations *via* co-authorship (Katz, 1994) thanks to a bibliometric analysis at the micro-scale. We therefore analyze the social and geographic diversification of the co-authorship network of researchers on a fine scale along the career.

The case study of 80 chemists' careers

We selected 80 researchers from two French academic laboratories in chemistry, who were CNRS[1] Research Director or Full Professor in spring 2018 (Table 1). These positions will be referred in the paper as "senior researchers" to simplify the vocabulary. This population was chosen for its comparability. It guarantees a certain work experience and a minimum career longevity: all studied researchers are at an advanced stage of their careers and well-established in their scientific field[2].

[1] French National Scientific Research Center (Centre National de la Recherche Scientifique)

[2] The French system can be characterized as a centralized and regulated labor market controlled by disciplines, close to the Italian and Spanish ones and very different from the US (Pezzoni *et al.*, 2012). Academic careers in France can be divided into three main phases: i) PhD thesis and postdoctoral positions (fixed-term positions) ; ii) "Maître de Conférences" and "Chargé de Recherche CNRS" which corresponds to "assistant professor"; access

In France in 2012, the average age of recruitment for assistant professor in chemistry was around 31 years old and those of full professor was around 42 years old[3].

The two studied labs are IC2MP (Institut de Chimie des Milieux et Matériaux) located in Poitiers, and LCC (Laboratoire de Chimie de Coordination) located in Toulouse (two cities in Western France). These structures share some similarities. Firstly, they benefit from an old history and have acquired an international reputation in their respective scientific specialties. IC2MP is the result of the merger in 2012 of five co-located laboratories, that were active for decades. LCC was born in the 1974 and has grown over decades without major changes in terms of organizational and scientific patterns. Secondly, the two labs are about the same size: each of them gathers around 250 members, including around 100 permanent ones. Although the total number of senior researchers is almost the same for the two labs (38 for IC2MP and 42 for LCC), their internal structure is quite different: IC2MP has few but big teams (5 research teams, with an average of 7.6 senior researchers) whereas the LCC has many but small teams (16 research teams, with an average of 2.6 senior researchers). In addition, IC2MP is a joint research center (CNRS-University) whereas LCC is a unit specific to the CNRS: this justifies the overrepresentation of full professors in Poitiers (29 out of 38 senior researchers) and of CNRS research directors in Toulouse (26 out of 42 senior researchers). In terms of gender, 72,5% are male, which is consistent with national distribution. 62% of the French academics in chemistry were male in 2018[4]: this share moves from 56% for assistant professors to 75% for full professors, highlighting the glass ceiling in academic careers (Sabatier, 2010).

Table 1. Descriptive about the population

	CNRS Research Director	*Full professors*	*Total*
IC2MP - Poitiers	Men: 6	Men: 26	Men: 32
	Women: 3	Women: 3	Women: 6
	Total: 9	*Total: 29*	*Total: 38*
LCC – Toulouse	Men: 14	Men: 12	Men: 26
	Women: 12	Women: 4	Women: 16
	Total: 26	*Total: 16*	*Total: 42*
Total	Men: 20	Men: 38	Men: 58
	Women: 15	Women: 7	Women: 22
	Total: 35	*Total: 45*	*Total: 80*

We collected all the publications (articles, reviews, letters, notes and editorial materials[5]) of the 80 senior researchers from the Web of Science Core Collection. Thomson Reuters' Web of Science is a well-known and reliable source in science studies to collect publications, frequently used to collect co-publication data. An initial cleaning was performed to avoid namesake bias: we kept 9310 publications, including 9206 co-publications. Most of variables in the publication database have been kept on its own (for instance the title, the year, the scientific journal, the list of co-authors), and some other variables needed an in-depth cleaning, as geography (see later). From the publication list of a scientist, we split co-authored articles into co-authorship pairs (Melin and Person, 1996). As we stand on a personal network perspective, we only interest in *ego-alter* relationships and do not consider relationships between *alter*: *ego* is one of the 80 studied

requires the person to hold a PhD; iii) "Professeur des Universités" and "Directeur de Recherche CNRS" which corresponds to "full professor", access requires the person to hold a "Habilitation à Diriger des Recherches" (HDR).

[4] According to the French Ministry of Higher Edcation and Research : http://www.enseignementsup-recherche.gouv.fr/cid129560/fiches-demographiques-des-sections-de-sciences-2017.html

[5] Articles represent 99,4% of the total number of publications.

researchers and *alter* are all the co-authors. Concerning scales of analysis, it is important to distinguish between "cosignature" and co-author: in cases where *ego* co-signs ten times with an *alter*, this relation weights one co-author and ten cosignatures.

Finally, as we focus on the publication and collaboration dynamics, we use the year of the first publication as the beginning of work career of each researcher. Although the 80 senior researchers all occupy the same position in spring 2018, they have unequal career length and started publishing at different decades: the longest career is 51 years and the shortest one is 12. We generated cohorts, gathering together researchers in periods of 10 years, according to their first year of publication. This allows integrating time in two complementary dimensions: the generation and the career stage. Indeed, senior researchers that occupy a senior position today started their careers in different historical contexts: the way science is conducted, and the place of publication activity have hugely changed since 1960's. Also, thanks to a panel approach, the career of each researcher is sequenced in years (the first year of publication is considered as t_0, the second year t_1, and so on) since the propensity of a researcher to develop networks is not the same according to its career stage.

Table 2. Publication and collaboration patterns according to gender, position, generation

			Gender		**Position**		**Generation**			
		All researchers	*Male*	*Female*	*Full professors*	*Research directors*	*1967-1976*	*1977-1986*	*1987-1996*	*1997-2006*
	Number of researchers	**80**	58	22	45	35	13	18	28	21
	Average length of career (years)	**31**	31	29	30	31	46	37	28	19
Publication patterns	*Number of publications*	**9310**	7316	1994	4208	5102	2865	2406	2634	1405
	Number of co-publications	**9206**	7219	1987	4137	5069	2832	2342	2634	1398
	Average number of publications per researcher	**116**	126	91	94	146	220	133	94	66
	Average number of publications per year and researcher	**3,78**	4,01	3,13	3,09	4,64	4,78	3,61	3,33	3,48
Cosignature patterns	*Number of cosignature*	**41628**	31 869	9 759	18 181	23 447	11 157	9 796	13 265	7 410
	Average number of cosignature per researcher	**520**	549	444	404	670	858	544	473	352
	Average number of cosignature per co-publication	**4,52**	4,41	4,89	4,39	4,63	3,93	4,18	5,04	5,3
	Number of co-authors	**14 783**	11 132	3 651	6 908	7 875	3 727	3 317	4 880	2 859
	Average number of co-authors per researcher	**185**	192	166	153	225	286	184	174	136
	Average number of new co-authors per co-publication	**1,61**	1,54	1,84	1,67	1,55	1,32	1,42	1,85	2,05
	'One-off' co-authors	**8574 (58%)**	6361 (57%)	2213 (61%)	4033 (58%)	4541 (58%)	2147 (58%)	1899 (57%)	2822 (58%)	1706 (60%)

Table 2 details descriptive statistics regarding their publication activities and co-authorship: the 80 senior researchers co-published 9206 articles in which they cosigned 41 628 times with 14 783 different co-authors. At the individual scale, each senior researcher published in average 116 publications in their career and 3,78 publications per year. For each publication, they collaborate in average with 4,52 co-authors, including 1,61 new co-authors. These descriptive statistics demonstrate a relative high rhythm of publication activities, and a very collaborative research. Many co-signatures consist of bringing together different scientific expertise not all held by one single person or team. In terms of volume, the majority of co-authors (58%) are 'one-off' partners, *i.e.* *alter* with whom *ego* collaborated only once. Bernela and Milard (2016) showed these 'one-off' co-authors often correspond to "second-rank" co-authors, that are often non-permanent positions and unknown by *ego*: the dominance of team level implies that some co-authors from partner teams are involved in the publication without interaction with *ego*.

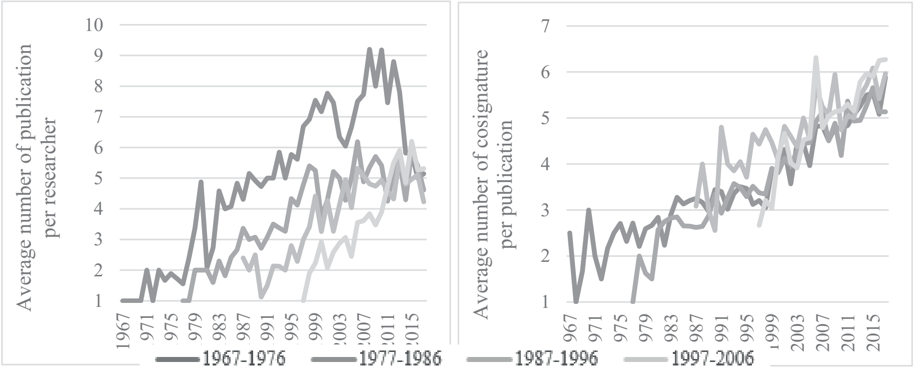

Figure 1: Dynamics of publication and cosignature patterns

Then, Figure 1 illustrates the dynamics of publication and cosignature patterns by generation. Although senior researchers did not start their career in the same historical context, all generations follow the same rhythm of annual publication all along their career. The annual rhythm of publication varies according to the career stage of the senior researcher and not to the generation. However, the collaborative dimension of publications depends on both the career stage and the generation of the senior researcher. Indeed, the average number of cosignature per publication increases throughout the career of each senior researcher. At the same time, the recent historical context encourages senior researchers to publish with more co-authors. For instance, in the 2000's, although the fourth generation just started to publish and the first generation started it more than thirty years ago, their publications had the same collaborative dimension.

From spatial information in publication data to mobility patterns and the geography of co-authorship

To reach our article objective - capturing the effects of mobility on the diversification of co-authorship - we need to define i) mobility patterns of the 80 senior researchers and ii) the geographical distribution of their scientific network (through the location of their *alter*) from the spatial information available in the WoS.

Before 2008, basic spatial information contained in WoS refers to the affiliations of co-authors in the form of a list of addresses, and there is no possibility to identify the address to which each author belongs. Moreover, the number of addresses does not necessarily correspond to the number of authors (several co-authors belonging to the same team, multi-affiliations of an author, etc.). Methodologically speaking, this absence of author-location matching implies that most studies focus on the address level only - how many cities collaborate in a publication? – to provide an understanding of the geography of science (Grossetti *et al.*, 2014; Maisonobe, 2015). It becomes a hindrance when studying geographical patterns of scientific trajectories. In our case, we used web search engines to collect all the locations of co-authors listed on a publication, at the scale of laboratory, city and country. This represents a time-consuming task of disambiguation, standardization and coding of database, necessary to obtain reliable geographical information. To our knowledge, it is the only way to question the geography of collaborations at the micro-level of researchers and has not be done yet, excepted Bernela and Milard (2016).

Among the corpus of 9206 co-publications, we resorted to web searches to allocate the location of *ego* and *alter* for had to manually search on the web for the 5 301 co-publications done before 2008. This job is already done for the 3905 publications after 2008. For each address, we kept three scales of geographical information: the laboratory, the city and the country. Concerning the laboratory, there was an important work of disambiguation: for instance, in the case of the Poitiers lab, “IC2MP” can also be registered as “UMR 7285” or the various names of old laboratories before merger. Finally, we kept multi-affiliations cases, i.e. when *ego* and/or *alter* is located in different laboratories in the same publication. In other words, a same couple *ego-alter* can be repeated several times for a publication but with a different geography, ensuring that the sum of co-signatures weights is equal to 1. Once locations of *ego* and their co-authors were cleaned for each publication, we can code the geographical distance between each pair of *ego-alter*. We break down this measure of distance into four increasing levels: lab, city, national, international. According to affiliations mentioned on publication, is *ego* located in the same laboratory, the same city, or the same country of *alter*? It allows to capture to what extent *ego* and *alter* share a common geographical environment. This micro-scale collection of data, consisting in coding the geographic distance between a researcher and its co-authors for each dyadic relationship makes our database an original tool for the geography of science.

Then, mobility is simply considered as a change in *ego* affiliation from a year to another, at the city level[6]. We are able to distinguish between infra-national and international moves. We identify the number of mobility along researchers’ careers (Figure 2): 19 out of 80 can be considered as sedentary researchers, i.e. without any change in location all over their career. We observe a concentration of mobility at the beginning of the career, highlighting the central role of postdoctoral positions in chemistry. In volume, there is as much international mobility as national ones. Some has never experienced mobility whereas others have moved a lot over their career, but it would not be satisfying to build binary categories of mobile/non-mobile scientists, as done in many articles (Aksnes *et al.*, 2013; Franzoni *et al.*, 2014; Chinchilla-Rodriguez *et al.*, 2018). Even mobile people were sedentary before their first mobility justifying the necessity to contextualize these events all along researchers’ careers to evaluate properly the impact of mobility on the diversification of co-authorship network. Moreover, we increment information about all the cities attended by *ego* in the past and are thus able to contextualize each publication (and co-authorship pair) in the geographic trajectory of the researcher. In a dynamic point of view, we can assess the continuance of relationships with *alter* from cities where *ego* was located before.

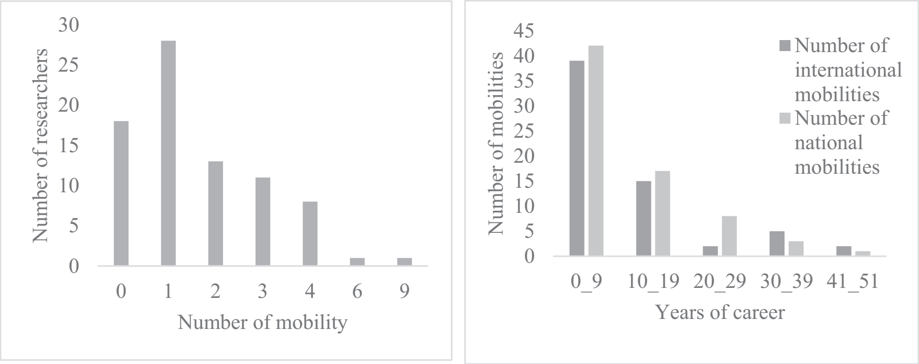

Figure 2: Number of mobility per researcher and during the career

[6] We do not observe institutional mobility within a same city, excepted changes of the lab name in the case of the merger in Poitiers.

Social and geographical dynamics of co-authorship over time

Before testing the impact of mobility on network diversification, it is important to understand the social and geographical patterns of co-authorship over the career (Figure 3): Figure 3a refers to the balance between new *alter* and former ones (*i.e.* with whom *ego* renews co-signatures) while Figure 3b refers to the spatial distribution of *ego-alter* relationships. On both figures, the upper curve refers to the growing trend of the annual mean of co-authors per publication over the career. Whatever generations, as researchers advance their career, the number of co-authors per publication rises.

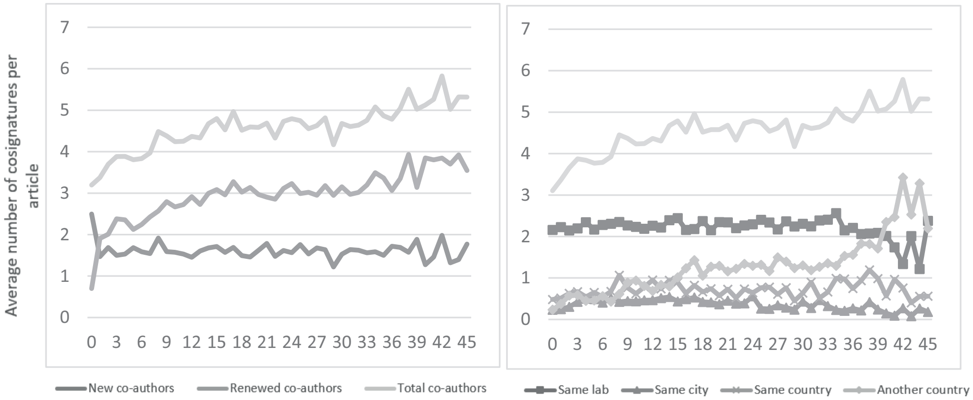

Figure 3: Renewal of co-authorship throughout careers / Geography of ego-alter relationships over time

The rise of co-authors per article throughout career stages is due to the continuance of relationships with some former co-authors, while the average number of new co-authors per article is very stable (around 1.5) over the career. Therefore, when they pursue their career, researchers do not increasingly collaborate with new co-authors but mostly with former ones as already observed by Cabanac *et al.* (2015). Concerning the spatial distribution of co-authors over the career and the distance separating *ego* and *alter* (Figure 3b) we note the important and stable weight of the *ego*'s lab colleagues (local co-authors) in the publication activity all along the career. Although non-local *alter* are a minority, their weight raises throughout the career: geographical openness of co-authorship occurs progressively with a frank internationalization for all generations. The densification of co-authorship is characterized by both a reinforcement of lab colleagues' core and an internationalization of co-authorship.

Table 3: Geography of *ego-alter* relationships

		Geography of *ego-alter* (%)						**Location of *alter* compared to *ego* trajectory (%)**				
		Same lab	Same city	Same country	Other country	Not found	Total	Current city	Attended city	Non-attended city	Not found	Total
New co-authors	n=14783	32,6	9,9	22,8	33,9	0,8	100,0	42,5	3,1	53,5	0,9	100,0
Total co-signatures	n=41628	49,8	8,7	16,1	25,1	0,3	100,0	58,5	3,3	37,9	0,3	100,0

Table 3 proposes a cross-analysis of the geography of co-authorship and the geographical trajectory of *ego*. If we look at the geographical context of the first cosignature between *ego* and *alter*, 42,5% of them happened with *alter* who was in the current city of *ego*. Only 3,1% are *alter* located in a former city of *ego*: after a mobility, *ego* does not seem maintain relationships with cities attended in the past to integrate new *alter* in its network. The main configuration (53,5%) is *alter* from a city where *ego* was never affiliated before, suggesting that mobility is far from being a prerequisite for the opening of the scientific network. Secondly, we observe the high “contribution” of local relationships: *alter* located in the city of *ego* at the moment of the publication represent 42,5% of co-authors and 58,5% of cosignatures: *ego* maintains relationships longer with local co-authors, with whom he cosigns on average more articles than non-local ones.

Econometric estimation and results

Our objective is to capture the impact of mobility on the diversification of network. The panel approach seems to be the most appropriate way to study individual evolutions based on our longitudinal data. We introduce an individual dimension, that represents each *ego* ($i \in N\,[0;80]$) and a time dimension ($t \in N\,[0;51]$), that represents each year of career of ego (the longest career is 51 years). After carrying out a Hausman test we chose to adopt a fixed-individual effect model. Indeed, the “within model” seems appropriate to focus on intra-individual evolutions: the focus on dependant and explicative variables at the individual scale permits to capture significant variations of the 80 trajectories whatever heterogeneity of publication and co-signatures patterns of researchers.

In order to capture the diversification of the co-authorship network, we measure annual flows of entrant and outgoing co-authors in the network. These two complementary dimensions allow us to evaluate the potential gains and losses of mobility experience on the network of senior researchers. Also, we chose to measure these flows as regards the whole network of *ego* (all *alter*) and more specifically *alter* coming from non-attended cities by *ego*. Then, we are able to evaluate the impact of mobility on *alter* who were integrated through the geographic trajectory of *ego* or not. So, our models estimate these following variables: $Y^{1}_{i,t}$ (average number of <u>new *alter*</u> per publication of the *ego i* in the year *t*), $Y^{2}_{i,t}$ (average number of <u>outgoing *alter*</u> per publication of the *ego i* in the year *t*), $Y^{1'}_{i,t}$ (average number of <u>new *alter*</u> coming from a non-attended city by *ego* per publication of the *ego i* in the year *t*) and $Y^{2'}_{i,t}$ (average number of <u>outgoing *alter*</u> coming from a non-attended city by *ego* per publication of the *ego i* in the year *t*). Table 4 details descriptive statistics of these variables.

Table 4: Descriptive statistics of dependent variables

	Direction of the flows	Variables	N	Mean	Std Error	Min	Max
All alter	Entry	$Y^{1}_{i,t}$	2099[7]	1,749	1,391	0	12
	Exit	$Y^{2}_{i,t}$	2099	1,728	1,654	0	15
Alter coming from a non-attend city	Entry	$Y^{1'}_{i,t}$	2099	0,857	1,101	0	10
	Exit	$Y^{2'}_{i,t}$	2099	0,822	1,187	0	10,5

Thanks to two temporal nominal variables, we characterize the mobility of the senior researcher in each year along the career. The first variable describes the dimension of the flow of mobility and the second variable reminds the year of the last event of mobility. These variables are complementary because they evaluate two effects of the mobility: immediate and delayed effects. In the results, we name models using the variable $X^{1}_{i,t}$ as model (a) and models using the variable $X^{2}_{i,t}$ as model (b). Table 5 describes the different modalities of these variables. We control our panel

[7] This value corresponds to the sum of the length of the 80 careers.

models with temporal variables dealing with patterns of publication and co-signatures of *ego i* : $Cosign_{i,t}$ (moving average of the number of co-signature per article of ego *i* between *(t-1), t* and *(t+1)), $Publis_{i,t}$* (moving average of the articles per year of ego *i* between *(t-1), t* and *(t+1)), $Geo\_net_{i,t}$* (number of cities of *alter* with which ego *i* has cosigned until (*t-1*)), $Social\_net_{i,t}$ (number of *alter* with which ego *i* has cosigned until (*t-1*)) and $Citat_{i,t}$[8] (number citations *ego i* received in (*t-1*)).

Table 5: Mobility variables

Variables	Modalities	Description of modalities
$X^1_{i,t}$ What kind of mobility ego *i* did in the year *t* ?	"not_mob"	Ego *i* kept the same city affiliation between *(t-1)* and *t*
	"National"	Ego *i* changed his city affiliation in *t* related to *(t-1)*
	"Internat"	Ego *i* changed his country affiliation in *t* related to *(t-1)*
$X^2_{i,t}$ When did happen the last event of mobility before the year *t* in the career of ego *i* ?	"sedentary"	Ego *i* never has been mobile until *t*
	"this_year"	Ego *i* has been mobile in *t*
	"1_to_3"	Ego *i* has been mobile between (*t-1)* and *(t-3)*
	"4_to_6"	Ego *i* has been mobile between (*t-4)* and *(t-6)*
	"7_to_9"	Ego *i* has been mobile between (*t-7)* and *(t-9)*
	"10+"	Ego *i* has been mobile before *(t-10)*

Results

Firstly, we observe that the mobility event (national or international one) stimulates the integration of new *alter* during the year of mobility. Indeed, in the model (1.a), the mobility gives a higher probability to have co-signatures with new *alter* (in comparison to years of non-mobility). However, this positive effect of mobility in the network diversification has a very limited duration. In the model (1.b), the mobility has a positive and significant impact only the year the mobility event occurs. The first econometric result is that integration of a new city has only an instant impact on the integration of new *alter*.

The model (2.b) shows that the mobility event has also a positive and significant impact on *alter* exits. Mobility has a more lasting effect on exit of co-authors than on entry, as the positive significant effect is observable for a mobility that occurred until three years before (model (2.b)). Mobility is both synonym of integration and destruction of relationships.

[8] This variable is based on the assumption of a linear distribution of annual citations, from the stock of citations of each publication received in 2018.

After testing our panel models on all *alter*, we restricted the analysis on *alter* located in cities non-attended by *ego*. In the last four columns of Table 7, we observe that mobility has no longer significant impact on the entry and exit of co-authors. So, the creation and rupture of relationship following a mobility only concern *alter* located in cities attended by *ego*. Although mobility allows diversification of the network, its geographical impact is limited to the cities where ego has been located all over its career: mobility does not provide extra bonus of diversification of scientific nerwork.

Discussion and conclusion

The objective of this article is to evaluate the impact of the mobility on the diversification of the co-authorship network. We used 9206 publications of 80 chemists to analyze their 41 628 co-signatures with 14 783 co-authors, at micro-scale. The goal is to evaluate the impact of changing city affiliation (mobility) on the entry and exit of co-authors in the network of researchers over their career.

Descriptive statistics suggest that the social and geographical patterns of co-authorship in chemistry are relatively stable whatever individual trajectories. Although the number of co-authors by publication grows over the career, the volume of new co-authors (social opening) is stable and the volume of former co-authors (continuance of relationships) raises. Moreover, the weight of the *ego*'s lab colleagues (local co-authors) in the publication activity is central and structuring all along. The densification of co-authorship goes with an internationalization process with career progress. However, the mobility does not seem having a premium effect on the diversification of the network. The share of *alter* located in cities attended by *ego* in the past is very low (interpersonal relations are hard to maintain in an experimental practice of science) and mobility does not seem to be a prerequisite for internationalization of co-signatures. Researchers tend to maintain relationship with local co-authors (in terms of co-signatures).

In the panel models, we evaluate the impact of mobility at the intra-individual scale. We see the experience of mobility increases the integration of new co-authors per article. However, this effect is only instantaneous: we do not observe a *premium* effect of mobility over time (Jonkers and Tijssen, 2008). The effect of integration is also restricted to the cities attended by *ego*: there is no "bonus" openness linked to the arrival in a new city. Chinchilla-Rodriguez *et al.* (2017) showed that the international trajectory of researchers is not responsible to his international co-signatures: the international network of mobility is three times smaller that the international co-authorship network. The second effect is that mobility weakens previous relationships and the "exit" effect lasts longer than the "entry" one.

These effects have to be taken into account when thinking about research policy and mobility incentives. Encouraging permanent/job-to-job mobility to expand the network of co-authorship seems counterproductive for two reasons. Firstly, mobility has a significant effect on the network, both on entry and exit: it destroys as many relationships as it creates. Secondly, these effects on the network only concerns co-authors integrated in the geographic trajectory of the researcher. Integrating a new city, the researcher creates only relationships with new lab colleagues and replace former ones. Ackers (2008) shows that in skilled scientific countries, mobility is considered as a sign of excellence only if the researcher had access to local skilled co-authors and had cosigned with them. However, the ability to collaborate with various cities does not depend on the mobility of the researcher. Therefore, short-term mobility should be encouraged because it seems so much powerful to create linkage between scientists.

Abstract

This paper presents a first attempt to analyse Open Access integration at the institutional level. For this, we combine information from Unpaywall and the Leiden Ranking to offer basic OA indicators for universities. We calculate the overall number of Open Access publications for 930 universities worldwide. OA indicators are also disaggregated by green, gold and hybrid Open Access. We then explore differences between and within countries and offer a general ranking of universities based on the proportion of their output which is openly accessible.

Introduction

The recent announcement by Science Europe of Plan S, an initiative aiming at providing open access to all publications funded by a group of funding agencies (Else, 2018a, 2018b), has refuelled interest on Open Access at all levels. While Open Access (OA) has been on the agenda of the European Commission for quite some time now (Moedas, 2015), their favourable position towards implementing Plan S (Rabesandratana, 2019) invites to believe that it will soon be also mandatory for all EU funded research. The strictness of Plan S requirements, raises doubts on its viability (Frantsvåg & Strømme, 2019). But still, it evidences the need to monitor OA compliance at all levels, including institutional level.

Universities have been supporting OA for many years now. The most common has been by building and maintaining institutional repositories, and introducing mandates that oblige their researchers to deposit their publications (Harnad, 2007; Harnad et al., 2008). Another more recent way by which institutions are promoting OA, is by sponsoring costs derived from the article processing charges (APC) of open journals (Gorraiz & Wieland, 2009; Gorraiz, Wieland, & Gumpenberger, 2012). In any case, institutions are still faced with the challenge of determining how much of the research they produce is actually openly accessible. Initiatives such as the ranking of OA repositories (Aguillo, Ortega, Fernández, & Utrilla, 2010) offer a partial information which, although valuable, is still insufficient. One of the main limitations is that researchers may combine green and gold OA, and even when self-archiving their publications, they may deposit them in different repositories, impeding institutions to track efficiently their output.

Until recently, there were no more than estimates as to the amount of publications which were available in open access. But the development of platforms like CrossRef, DOAJ or even Google Scholar, along with computational advancements on web scraping, have led to a plethora of large-scale analyses to empirically identify OA literature (Archambault et al., 2014; van Leeuwen, Tatum, & Wouters, 2018; Martín-Martín, Costas, van Leeuwen, & Delgado López-Cózar, 2018; Piwowar et al., 2018). Overall, these studies report that around half of the scientific literature is freely available, but point towards the increasing availability of publications which do not adhere strictly to what is considered OA.

Here we highlight Unpaywall (Piwowar et al., 2018), which has had a great impact after being implemented by most of the main bibliometric data providers (Else, 2018c). Furthermore, the fact that the Unpaywall API can be freely queried allows others to assess on its performance but also to build on it. In this paper, we present a first attempt at analyzing Open Access at the institutional level, not only in general, but also focusing on the two main routes of OA: the green and the gold route; plus hybrid OA. The purpose for doing so is not only to inform university managers and funding agencies on the level of OA implementation of universities, but also to be able to understand and analyse national trends, and institutional strategies to implementing OA. Although we identify bronze OA, we exclude from our analyses due to the issues related with the sustainability of this type of OA, raising doubts as to its viability from a policy perspective (van Leeuwen, Meijer, Yegros-Yegros, & Costas, 2017)

Data and methods

In this paper we use different sets of sources and combine different methods to determine Open Access. The set of universities analysed and the identification of their publications is retrieved from CWTS in-house version of the Web of Science, based on the institutional name disambiguation developed to produce the Leiden Ranking (Waltman et al., 2012). For each publication, we identify if they are openly accessible and the type of Open Access by querying the Unpaywall information. The Unpaywall API does not labels types of OA but describes what information was derived from each record. More information on the information provided is available at their website the User Guide offered for researchers (http://unpaywall.org/data-format).

The labelling of OA types is described in Figure 1 and already highlights some of the difficulties and controversies raised when trying to define what is actually Open Access (Torres-Salinas, Robinson-Garcia, & Moed, 2019).

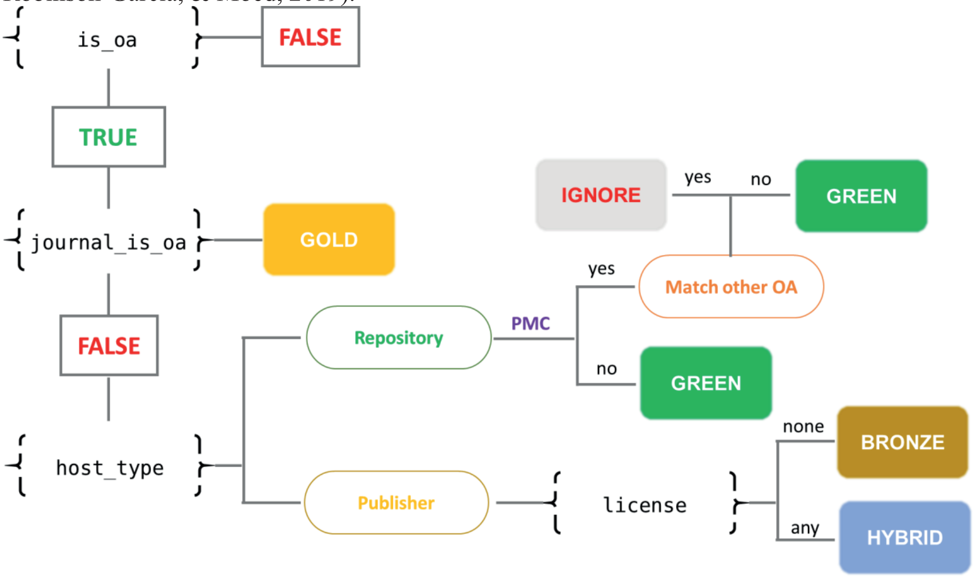

Table 1. Conditions included to determine type of Open Access and total publications retrieved for the 2014-2017 period for our set of 930 universities

	journal_is_oa (Unpaywall)	*evidence* (Unpaywall)	*Gold_OA* (Leeuwen et al. 2017)	Type of OA	Total pubs
∪	TRUE	--	TRUE	Gold	645,547
∩	FALSE	open (via free pdf)	--	Bronze	449,929
∩	FALSE	open (via crossref license, author manuscript)	--	Undetermined	49,697
∩	FALSE	open (via page says license)	FALSE	Hybrid	121,637
		oa repository (…)		Green	562,747

As table 1 shows, four types of OA were considered plus an *undetermined* category which included a segment of publications which were hybrid, bronze and sometimes even gold OA which were impossible to discriminate from by using the fields offered by Unpaywall. These four types of OA are defined as follows:

		Total pubs		Total OA			Green OA			Gold OA			Hybrid OA

Figure 1. Institutional output at the country level for those countries with at least 10 universities in the dataset for the 2014-2017 period. Countries are shown based on the number of universities included in the ranking. Arrows show changes in ranking based on average of total number of publications

- **Green Open Access**. Self-archived versions of a manuscript. Here the responsibility lies on the author who is in charge of depositing the document in a repository. This version of the document may not correspond with the final version of the publisher.
- **Gold Open Access**. This refers to journals which publish all of their manuscripts in Open Access regardless of the business model they follow (e.g., publicly sponsored, author pays).

- **Bronze Open Access**. While again journals are the ones offering the publication freely available, this is not subjected to copyright conditions set to be defined as Open Access (i.e., they do not ensure perpetual free access).
- **Hybrid Open Access**. Non-OA journals make specific publications openly accessible usually after the author pays a fee to account for potential losses derived from subscription fees.

In all, a total of 930 universities were analysed for the 2014-2017 period. While we identified some overlap between green and gold OA, the other three categories are exclusive from each other. Finally, in this paper we will consider as OA whichever document which adheres to any of these five types, however we will offer a deeper analysis to those following the green and gold routes. The rationale for this is that these two routes are, in principle, the ones that more closely align with Plan S and with the development of a sustainable movement towards full Open Access.

Results and discussion

The two countries contributing most on the number of universities analysed are United States and China, more tripling the third and fourth countries (Figure 1). The Netherlands have on average the most productive universities followed by United States, Australia and Canada. While this trend is followed on the average number of OA publications, there are important changes on the average output of OA publications they should produce considering their total output. For instance, British universities occupy higher positions when referring to total, green, gold or hybrid OA output on average. However, there seems to be large disparities within the country. On the other side we find countries such as Australia, Canada and China, which are in a lower position based on their average number of OA publications than what they should occupy, according to their overall average number of publications. We find differences on the size of the output of institutions by country. While this is to be expected, we do find more or less disparity when focusing only on OA publications. For instance, there is a greater deviation from the average for Turkish universities when considering only green OA publications, while the deviation is consistently higher for Chinese universities when focusing on any type of OA than when considering all publications. An interesting case is the one observed in The Netherlands, which the country where its universities produce on average the highest number of OA publications, despite falling back on both, green and gold OA. Still, it maintains its first place with regard to the average number hybrid OA publications.

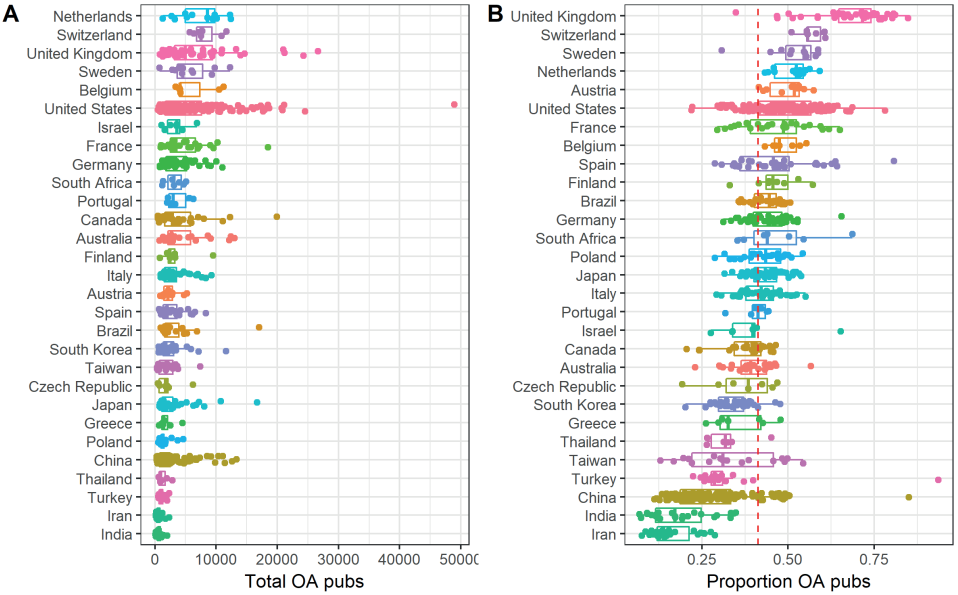

Figure 2. Distribution of universities based on their A) total number and B) proportion of OA publications for countries with > 5 universities included. Countries ordered by median proportion of OA publications. Red dashed line shows world median.

Disparities within countries are further analysed on figures 2 and 3. Here we plot for the distribution of universities by country for their total and proportion of OA publications and by green and gold OA. Overall, we observe that the United Kingdom is the country in which their universities are making a higher proportion of their publications openly available, followed by Switzerland and Sweden (Figure 2B). Furthermore, we find extreme cases in Turkey and China with two universities having virtually all of their output OA. In these two cases, most of the universities show shares of OA lower than the world median. It is also worth noting that most of the countries with higher proportions of OA at the institutional level are European with three notable exceptions. These are Brazil, South Africa and United States. In the case of the two former, we find a very different pattern from the other two BRICS countries shown (China and India), which have a proportion of OA publications below world median. In the latter case, it does not occupy a leading position as it is usually the case with the United States. Russia is not present in these figures as only two universities are included in our dataset.

The ways in which universities are making their publications openly accessible varies greatly when distinguishing between gold and green OA. United Kingdom and Switzerland are again the ones with a higher median on the proportion of green OA their publications have (Figure 3B). Belgium and especially Spain, outstand in third and fourth place with respect to their overall proportion of OA. It is also worth noting the great dispersion on proportion of green OA not only between countries but also within countries. While the world median proportion of green OA is 8.7%. It raises up to 22.1% for the United Kingdom and it is 3.1% for Iran.

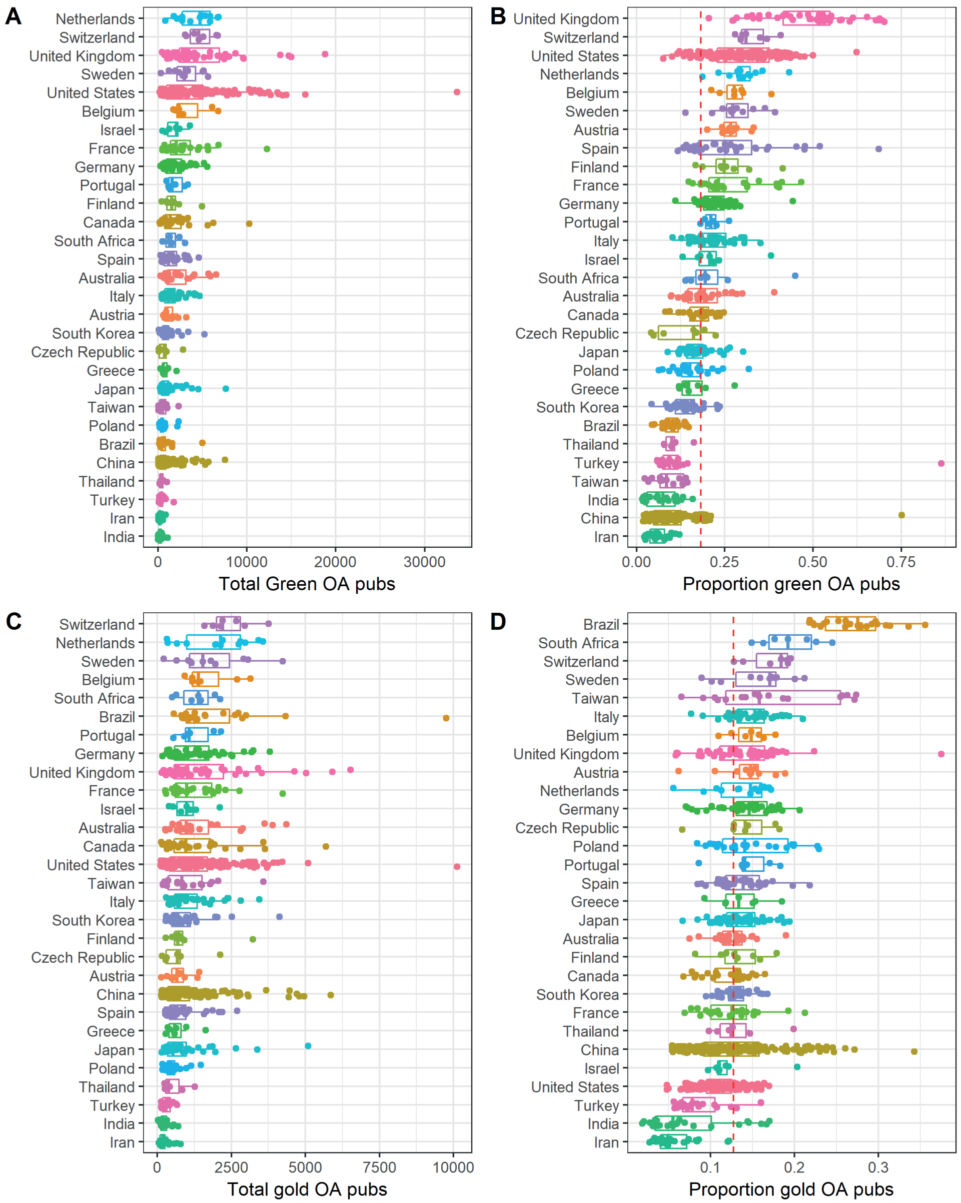

Figure 3. Boxplots by country for countries > 5 universities included based on their A) total number and B) proportion of green OA pubs and C) total number and D) proportion of gold OA pubs. Countries ordered by median proportion of OA publications. Red dashed line shows world median.

In the case of gold OA, the world median institutional share is 11.8%. As observed, there are less disparities within countries than in the case of green OA (figure 3D). In this case, Brazil (26%), South Africa (19%) and Taiwan (17%) are the countries with the largest proportion of their output in gold OA (median values). China is the country with greater disparities between its universities. To better interpret the patterns of these countries we look into the OA journal profile of these four countries, following the three models of gold OA proposed by Torres-Salinas, Robinson-Garcia, & Moed (2019). The first one refers to countries which publish in OA journals owned by publishing firms, preferably mega-journals and with a high Journal Impact Factor. The second model is that of countries which publish in OA journals edited in their own country, preferably in their native language and publicly funded. The third model is a mixed one where gold OA publications are channelled through both OA mega-journals and nationally-oriented OA journals. In all cases but China (where it is second behind *Scientific Reports*), *PLoS One* is the journal with the largest number of publications. In the case of Brazil, the rest of OA journals in the list are in a vast majority Brazilian journals listed in SCielo. In South Africa we observe a combination of regional journals and big OA publishers. Finally, China and Taiwan exhibit a greater reliance on journals from big OA publishers such as Nature Springer, PloS, MDPI or Hindawi.

Finally, we conclude by showcasing in figure 4 the top 50 universities with the largest proportion of OA worldwide. These 50 universities come from 12 different countries. More than half of them come from United Kingdom (26), including major universities such as London City University. Next, Spain positions 6 universities, followed by France and the United States (5 each). While the remaining countries have only one university included in this top 50. Here we note that the two outliers aforementioned from Turkey and China (figure 2B), are actually the top 2 universities on openly accessible literature, mostly relying on green OA (see figure 3B).

Concluding remarks

This paper presents a first attempt at measuring OA uptake by universities worldwide. Europe is hardening its policies towards full OA, and initiatives such as Plan S are being supported by important international funding bodies (e.g., Wellcome Trust, Bill & Melinda Gates Foundation). The introduction of such policies may affect differently across Europe and such policies may expand to other countries. The inclusion of indicators on OA to the Leiden Ranking adds another dimension, which is less traditional, and focused on changes in scholarly communication practices. This can better inform how OA is being implemented and which routes are having a greater implementation. Finally, this contribution allows to study the distribution across the globe of OA uptake, to what extent the initial goals of the OA movement to distribute more equally over the globe reached, especially when looking at OA uptake in e.g., the Global South, effects of regulations (e.g., inclusion of hybrid OA by Plan S), etc.

Here we present a first attempt at developing OA indicators at the institutional level globally. However, there are many issues that still need to be dealt with. For instance, the consideration of Unpaywall as the most important means by which OA is captured, although welcome and remarkable, needs to be better assessed and understood (double occurrences, *undetermined* category, etc.). Also, it is important to understand better and make more distinct in OA analyses gold OA models and specifically publicly-funded gold OA (i.e., SCielo) versus APC models and private publishing firms.

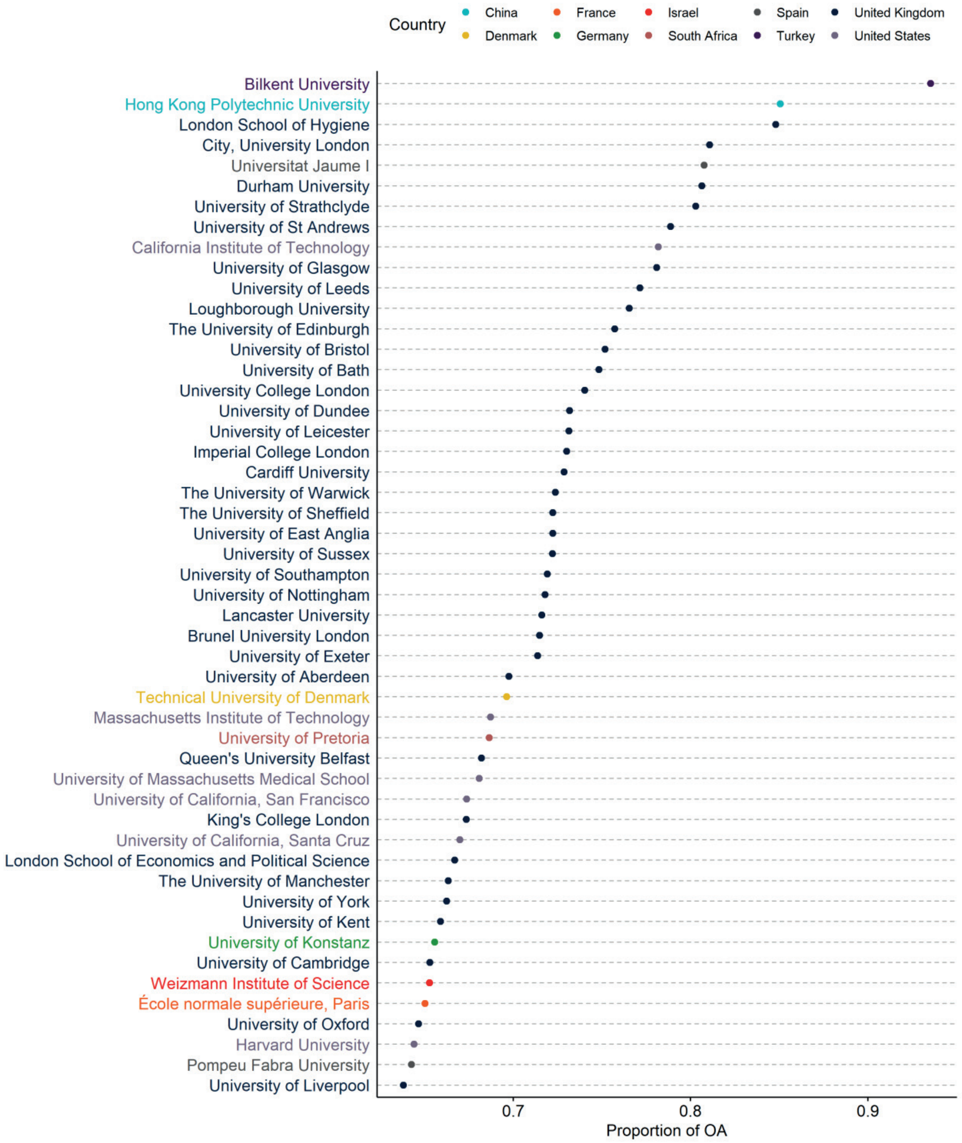

Figure 4. Ranking of top 50 universities based on the proportion of Open Access publications in the 2014-2017 period

Research on the relationship between citation and altmetrics of Open Access Papers from different geographical regions

Jingda Ding and Jie Guo and Xinjing Liu and Xiangjie Ma and Chao Liu

djdhyn@126.com

Department of Library, Information and Archives, Shanghai University, Shanghai 200444, China

Abstract

With the development of open access, more and more scientific papers are published in journals as *PLoS* and are freely available by online. Analyzing the relationship between citation and altmetrics of open access papers published on *PLoS* in recent 10 years by the 6 countries which are selected in terms of regional distribution, scientific level and native language etc., we induced the following conclusions: First, the different geographical regions have effect on the citation and the altmetrics of 'view' and 'save' (excepting 'share'), because the means of them for developing countries are less than that of developed countries in last 10 years and the curve peaks of these 3 indicators of different countries occur in different years. Second, the citation and the altmetrics of 'view' and 'save' are significantly correlated with each other and have the similar variation patterns and accumulate with year, while the altmetrics of 'share' is just opposite. Therefore, to some extent the altmetrics of 'view' and 'save' can evaluate scientific influence as a complement of citation, and the 'share' of *PLoS* papers seemingly just reflects the attention/mention of user rather than the academic influence because it is transient and uncorrelated with the citation.

Introduction

Traditional bibliometric analysis and peer review have formed the standard methods to assess the 'scientific status of disciplines'(Patel & Chavda, 2016). The number of publications, citation frequency and peer review are traditional science measurement indicators. Since Garfield came up with citation analysis, it has received a lot of popularity. The frequency of citation partly inflects the academic value and influence of research papers through the reference relationship between them. Thus, citations qualify the quantity of publications and this makes it a good indicator to rank publications' value(Lehmann, Jackson, & Lautrup, 2006). As is known, citation analysis also has some deficiencies, but it is still a good method to evaluate the research impact, and some citation indicators such as h-index(Hirsch, 2010) , journal impact factor (Garfield, 1972) have been used for research evaluation though controversial(Garfield, 1999; Leeuwen, 2005). Now, some scholars have suggested that citation is not able to reflect the broader impact of research (Holmberg, Didegah, & Bowman, 2015), can't meet and satisfy the development requirements of the era of web 2.0+.

In the era of Web 2.0, more and more scholars tend to share experiences, express ideas, or disseminate research findings at different social media, such as *Blogs*, *Twitter*, *Facebook* and so on. With the use of these new tools in scientific communication, traditional biblometric analysis and peer review are not enough to evaluate the impact of scientific publications in social media. In this context, alternative metrics, also called "altmetrics", was proposed by Priem and his collaborators at the first time in 2010, and they noted that altmetrics are the creation and research of a new kind of metrology, based on the analysis and dissemination of research production in social network(Priem et al, 2010). Altmetrics are the new metric to evaluate the influence of scientific publications, which discussed, shared, posted, tagged, mentioned or tweeted on social media platforms. According to Work et al.(2015), altmetrics are usually based on activity on online communication platforms, relating to scholars or scholarly content. Typical examples of altmetrics include tweets, mentions in *blog* posts, readership counts on *Mendeley*, posts, likes and shares on social media such as *Facebook* and *Google+*, and recommendations and ratings on *F1000*. Altmetrics are usually considered as the subset of Scientometrics and Webometrics, and they are used to carry out Article-Level Metrics research (Stransky, 2016). According to the collected data of social media platform, altmetrics can evaluate the popularity or social influence of publications(Chavda & Patel, 2016). As Altmetrics, Inllumetrics, Entitymetrics, Usage metrics, Article-level metrics and other terms having been proposed(Glanzel & Gorraiz, 2015), the evaluation of research paper can not only rely on the amount and its citation count(Moed & Halevi, 2015). Multi-source and multidimensional of the measurement in research is the trend.

Based on those, we propose the following two questions and try to solve:

1. What is the relationship between citation and altmetrics of open access papers?

2. Do different geographic regions have an impact on citation and altmetrics of open access papers? If so, what are the key influencing factors?

Literature Review

The researches on relationship between citation and altmetrics for traditional journals are more than that based on the new environment of Open Access (OA), so it is worth spending time to do further study that based on the OA papers from different cultural background. In the context of OA movement, free online availability of scientific literature offers substantial benefits to science and society(Lawrence, 2001), and researchers can join many different websites to publicize their research productions(Thelwall & Kousha, 2017). In the early stage, the research on OA thesis mainly focused on the impact of OA papers. Through the comparison of open access and non-open access(non-OA)(Davis, Lewenstein, Simon, Booth, & Connolly, 2008; Moed, 2007; Norris, Oppenheim, & Rowland, 2008), the value of open access can be understood(Joint, 2009). OA papers have reached or even more than non-OA papers of quality and influence(Hu, 2008). This is a huge advantage in sense of scientific dissemination: each article may receive as wide readership as it deserves, and does not matter whether the journal impact factor is high or low. Yassine et al.(2010) analyzed of 27,197 articles published in internationally peer-reviewed journals, and found out that the open access had significant effect on citations in different scientific disciplines. OA publications obtain more citations compared with those not openly accessible. From the investigation of 15 countries(Shu, 2017), there are 14 countries in which twitter papers cited quantities excess 30% than non-twitter papers. Hence, the influence evaluation of OA papers is more closely related to the new measurement index by comparing with traditional paper. Researches on altmetrics and their possible implication in calculating the influence of publication are becoming widely (Priem et al, 2010; Chavda & Patel, 2016). And scholars are attaching more and more importance to the correlation between citation and altmetrics (Dhiman, 2015; Peters et al.,2016;Waltman & Costas, 2014; Thelwall et al., 2013). Some scholars investigated the correlation from different disciplines like social science, medical science etc., while others analyzed the correlation between different kinds of altmetrics indicators and citation. Costas, Zahedi &Wouters(2015) found that the mentions in blogs and news outlets had a relatively stronger correlation with citation than other altmetrics indicators. Syamili et al.(2017) explored the correlation of citation and altmetrics based on a specific topic about "Ebola", and pointed out that the Twitter count had no correlation with citation frequency while other altmetrics values had the good correlation with it. It seems that altmetrics like tweets, mentions and readership counts (on *Mendeley*) might reflect the impact of publications in society or the public attention, while their connection with the quality of research(often be evaluated by citation frequency) is loosely even none(Bornmann, 2015). Compared to citation, which exists a long time delay, *Twitter* begins to tweet papers in several of days even hours after published, which shows that altmetrics coming from *Twitter* etc. seemingly tends to reflects the attention/mention rather than the academic influence in a short time. And there are more and more scholars to study the impact factors of the correlation between citation and altmetrics (Dhiman, 2015). Peters et al.(2016) surprisingly found that altmetrics had no correlation with citation, which may not correspond to the positive but relatively moderate correlation results in the study of other scholars(Waltman & Costas, 2014; Thelwall et al., 2013). The reasons for different analysis results may be various factors that influence the correlation of citation and altmetrics, such as the year of publication, discipline, user types and habits, different social media platforms and so on. At present, even though the use of altmetrics in measuring the scientific research still in controversial, some areas (Chisolm, 2017; Wang, Alotaibi, Ibrahim, Kulkarni, & Lozano, 2017) have started to bring altmetrics in their own research field to evaluate journals and get the popular magazines of their own field.

In a word, the citation has a positive but is relatively weak correlation with altmetrics, and different kinds of altmetrics indicators have different degree of correlation with citation. However, there is little research that consider whether different cultures or regions have effect on the correlation between them. Researches on regional distribution difference often focus on geographical collaboration at department, institution and national level and the distribution of authors(Abbasi & Jaafari, 2013; Bartneck and Hu, 2010; Gorraiz, Reimann, & Gumpenberger, 2012). There are few of scholars in-depth discussing the differences of the correlation between citation and altmetrics among countries. Based on that, this work analyze the relationship between citation and altmetrics of OA papers from the perspective of different countries.

Research Methodology

PLoS is an open-access journal platform based on peer review, which is about biology, medicine and some diseases. There are 'citation', 'view', 'save' and 'share' in *PLoS ALM* dataset. The 'citation' is the sum of citation count of *Scopus* and *Crossref*, the 'save' is the number of *Mendeley* bookmarks, the 'view' is the total number of page views and downloads of *PLoS* and *PubMed Central*, and the 'share' is the discussion counts by *Twitter* and *Facebook*, which are records of different aspects of the *PLoS* papers. In the article, we selected the papers published in 6 *PLoS* journals by 6 representative countries between 2009 and 2018 as the research sample. These 6 journals are *PLoS Biology*, *PLoS Computation Biology*, *PLoS Genetics*, *PLoS Medicine*, *PLoS Neglected Tropical Diseases and PLoS Pathogens*, which belong to the field of biomedical technology. These 6 countries—Brazil, China, Germany, Japan, Russia and USA are selected, because China and Brazil are developing countries while Germany, Japan, Russia and USA are developed countries. In addition, Germany is located in Europe, Russia spans the Eurasian continent, USA and Brazil pertain to America, and China and Japan belong to Asia, and USA is the English-speaking country while other countries are not. Given that the value of ‘view’, ‘save’, ‘share’ and ‘citation’ would be changed with time, the deadline we collect data is April 19, 2019. Table 1 presents the quantity of papers published on *PLoS* journals by the 6 countries in every year.

Table 1. The number of papers published by the 6 countries in each year

Results

Descriptive Statistics

From Table 1, we can see that the quantity of the United States is much higher than the other countries, and the number of papers published by each country keeps growing though there is a slight fluctuation in recent 5 years. Figure 1 displays the percentage of paper published by each country in every year. Although the number of papers in each country is growing, the proportion of papers published annually (based on the total number of 6 countries in this paper) varies. As can be seen from Figure 1, China and Russia are on the rise, Brazil and Japan remain stable. For the United States and Germany, they show the different change, the former was falling until to 2016, the latter was increasing in stability before 2016 and decreased in latest 2 years. Generally, as a scientifically developed country, the amount of papers published by the United States is far ahead. Germany is the second though still far behind the United States, China is slightly more than half of Germany’s, Japan is close to Brazil with the approximately annual output of 1000 or so, which are fourth and fifth respectively, Russia is the least.

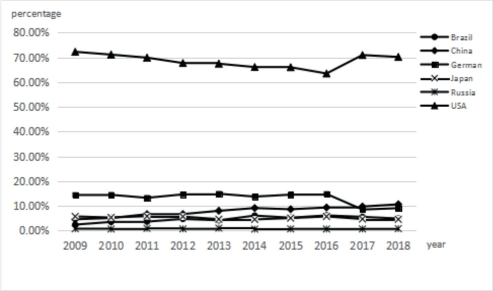

Figure 1. Percentage of papers in each year

Figure 2 is the ratio of the United States and other five countries in the 6 *PLoS* journals, which shows the advantages and disadvantages of each country in biomedical domain. In the 6 countries, Brazil's development is extremely unbalanced, whose number of papers published in *PLoS Neglected Tropical Diseases Journal* is more than the other 5 journals. China is similar to Brazil, whose number of papers published in *PLoS Genetics Journal* is more than the other 5 journals. Germany's paper number in *PLoS Medicine Journal* is less than the other 5 journals, as do China, Japan and Russia. The United States publishes a relatively balanced number of papers in these six journals and has obvious advantage.

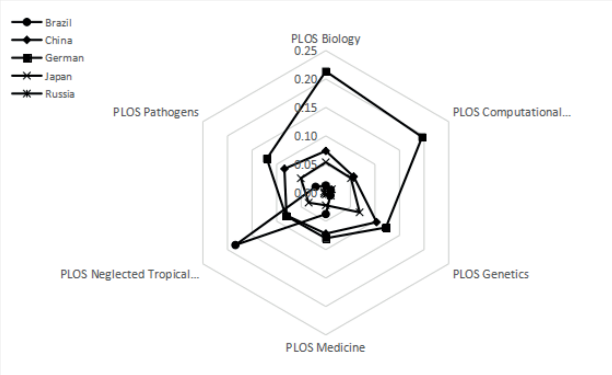

Figure 2. Distribution of publications in the 6 journals of each country

Mean and Coverage Degree

Different kinds of altmetrics indicators of *PLoS* papers had different coverage, which refers to the ratio of a non-zero count of some indicator of papers to the total number of the sample papers, measuring the distribution breadth of the indicator on sample papers. Table 2 shows the mean value and coverage of the 6 countries from 2014 to 2018 and from 2009 to 2018. The mean and coverage of 'citation', 'view' and 'save' in recent 10 years are higher than or equal to that in latest 5 years, while 'share' is just the opposite, which indicates that the life cycle of 'share' is shorter than that of the others. The coverage of 'view' in each country are 100%, which testifies that each paper published by the 6 countries has been viewed and downloaded in *PLoS* and *PubMed Central* at least once. And the coverage of 'citation' is more than 91% in different countries, which presents that open access papers are easily accessible and thus cited. Only the coverage degree of 'share' is relatively lower, which is no more than 85% and there are significant differences between the latest 5 years and the recent 10 years.

Correlation analysis of Citation and Altmetrics

Table 3 lists the correlation coefficients of citation with ‘view’, ‘save’ and ‘share’ in each country. We can see that the citation has strong correlation with ‘save’ or ‘view’, while its relevancy with ‘share’ is very weak even none.

Table 3. Correlation coefficients between different indexes of the 6 countries

Cor.	*View*	*Save*	*Share*
Citation (Brazil)	0.714556995**	0.756788094**	0.076196384*
Citation (China)	0.755038197**	0.808202254**	0.002956998**
Citation (Germany)	0.735796999**	0.737906617**	-0.192310765**
Citation (Japan)	0.762207350**	0.753003825**	-0.179578338**

Compare analysis between Citation and Altmetrics for the 6 Countries

Figure 3 depicts the changes of ‘citation’, ‘view’, ‘save’ and ‘share’ with time in each country. The lateral axis expresses the year, the left vertical axis represents the number of ‘view’ and the right vertical axis represents the value of ‘citation’, ‘save’ and ‘share’. The units of vertical axes vary from different countries in order to make the overall change of index clear in each country.

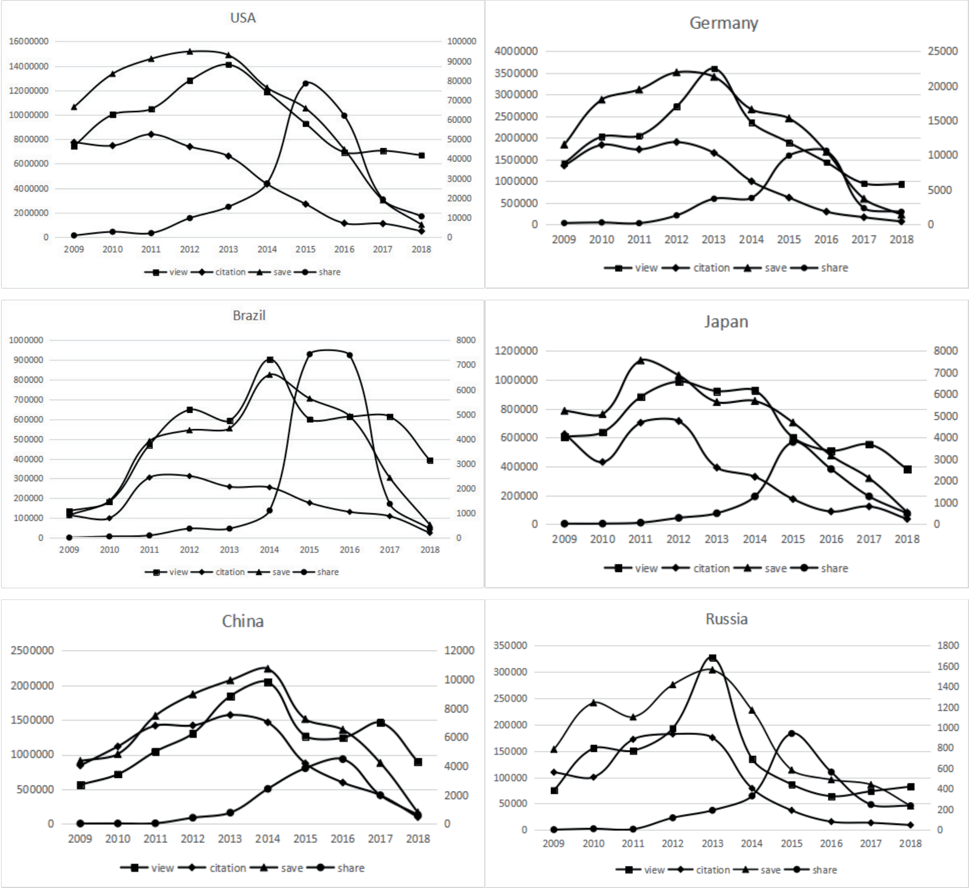

Figure 3. Changes of citation and altmetrics with year for the 6 countries

As can be seen from Figure 3, the curve peaks of 'citation', 'view', 'save' and 'share' of each country occurred in different years. Among them, the 'citation' peak of the United States occurred in 2011 and the maximum citation age of *PLoS* papers published by the United States is 8 years because 2019 is the observational year, i.e. these papers are active and vigorous in the latest 8 years after publication. Similarly, the 'citation' peaks of Germany, Brazil, Japan, China and Russia respectively occurred in 2012, 2012, 2012, 2013, 2012, accordingly whose maximum citation age separately is 7,7,7,6,7 years. Then the 'view' peaks of the United States, Germany, Brazil, Japan, China and Russia respectively occurred in 2013, 2013, 2014, 2012, 2014, 2013, and the 'save' peaks of them respectively occurred in 2012, 2012, 2014, 2011, 2014, 2013, and the curves of 'share' in 6 countries reached their peaks in 2015 or 2016. We can draw Table 4 from Figure 3. As a whole, the *PLoS* papers for each country firstly reach the 'share' peak after publication for 2 years or 3, then reach the 'save' or 'view' peak after 5 or more years, finally reach the 'citation' peak.

Table 4. The year in which the index peak appeared of the 6 countries

Peak	*USA*	*Germany*	*Brazil*	*Japan*	*China*	*Russia*
Citation	2011	2012	2012	2012	2013	2012
View	2013	2013	2014	2012	2014	2013
Save	2012	2012	2014	2011	2014	2013
Share	2015	2016	2015	2015	2016	2015

(Note: the date of collect data is April 19, 2019)

On the other hand, the curves of 'citation', 'view' and 'save' nearly keep the similar fluctuation trend, and exist the significant correlation between 'citation' and 'view' or 'save', which demonstrates that there are greater similarity of change among them. Differently, the curves of 'share' in 6 countries start to grow obviously from 2011 and reach their peaks in 2015 or 2016(until to the date analyzed), and there is no significant correlation between 'citation' and 'share'.

Discussion

This article is mainly to analyze the relationship between citation and altmetrics, and explore whether the different geographical regions have effect on the 'citation', 'view', 'save' and 'share', so as to improve the quality of research evaluation. Hence, we discuss the following 3 points.

The influence of different geographical regions on the 'citation', 'view', 'save' and 'share'

As shown in table 2, the average values of 'citation', 'view' and 'save' of China and Brazil are lower than that of the United States, Germany, Japan and Russia from 2009 to 2018, the former are developing countries and the latter are developed countries. Therefore, the geographical regions have effect on these three indicators because different countries have different cultural backgrounds, information behavior habits and even the quality of papers. But the 'share' is an exception, the 'share' of Brazil are the biggest among the 6 countries in 10 years period, which may due to that Brazil published more papers in *PLoS Neglected Tropical Diseases Journal* than the other 5 journals.

Figure 3 and Table 4 display that the peaks of 'citation', 'view', 'save' and 'share' are different among the 6 countries. For the 'citation', the peak of the United States occurred in 2011 and the maximum citation age of the papers published by the United States is 8 years, i.e. these papers are active and vigorous in recent 8 years after published. The peak of China occurred earliest among the 6 countries, whose maximum citation age is 6 years. These manifest that the different geographical regions also influence the time of active and vigorous of papers.

The relationship among the 'citation', 'view', 'save' and 'share'

The means of the 'citation', 'view' and 'save' of *PLoS* papers in recent 10 years are bigger than that in latest 5 years among the 6 countries in Table 2, which indicates that these three indicators have the common characteristic as their values all increase with the extend of publication time. However, the change of 'share' mean is on the contrary. Although articles will be shared quickly in 1 year or 2 after published, they will not be mentioned anymore as time goes on, i.e., the ‘share’ is transient and timely, whose life cycle is shorter than that of the other 3 indicators.

Table 3 and Figure 3 also show that ‘citation’, ‘view’ and ‘save’ have significant correlations and similar variation patterns and accumulate with time for the 6 countries, i.e. the newly published papers need a maturity period to get more ‘citation’ (Syamili and Rekha, 2017), ‘view’ and ‘save’. Hence, we could induce that the ‘view’ and ‘save’ --- two kinds of altmetrics index, can evaluate the scientific influence as a complement measurement of traditional citation analysis, though they do not reflect the same kind of impact as citation(Costas, Zahedi, & Wouters, 2015). Due to the convenience of open access platforms like *PLoS* and the wide use of online reference managers such as *Mendeley*, *Endnote* and *CiteULike* etc., more and more readers can easily access the scientific papers, and freely view, download or save in *Mendeley* etc. Though the role of open access and social media in promoting dissemination of scientific papers couldn’t be ignored, we should be careful not to overstate the value of altmetrics. Cameron(2015) said that scientific assessor should recognize the limitation of altmetrics when using it to evaluate the influence of country, institution and individual. As analyzed in this paper, the ‘share’ has no significant correlation with citation in this paper.

The analysis of the ‘share’

The ‘share’ of *PLoS* platform means that the total number of a paper discussed or mentioned by *Twitter*, *Facebook* etc. It can be seen from Table 2 that the mean of ‘share’ of papers published in latest 5 years is more than that in recent 10 years, the curves of ‘share’ for the 6 countries start to grow from 2011 and quickly reach their peaks in 2015 or 2016 (the date of collect data is April 19, 2019) in Figure 3. So the articles published in latest 5 years, especially in latest 3 years would be discussed easily by the users of *Twitter*, *Facebook* etc., i.e., the life cycle of ‘share’ of *PLoS* papers is short, which can be instantly tweeted after publication, while their citation need a the long time to accumulate. Moreover, considering the weak correlation between ‘share’ and ‘citation’ according to Table 3, we believe that the ‘share’ of *PLoS* papers seemingly just reflects the attention/mention of user rather than the academic influence.

Conclusion

Through analysis of the Article-Level Metrics data of papers published in *PLoS* series journals by different countries, the following conclusions are shown: Firstly, the geographical region has effect on the citation and the altmetrics of ‘view’ and ‘save’ (excepting ‘share’), because the mean of each of them in China and Brazil is less than that in USA, Germany, Japan and Russia from 2009 to 2018, and the curve peaks occurred in different years among the 6 countries. As is known, the former two are developing countries while the latter four are developed countries, and the United States is the only one whose native language is English of the 6 countries. Hence, we induced that the level of scientific development in different countries has more effect to these 3 indicators than the native language. For example, with the rapid development of science and technology in China, whose mean of citation has been slightly higher than the developed countries in latest 5 years. Secondly, ‘citation’ and ‘view’, ‘save’ are significantly correlated with each other and have the similar variation patterns and accumulate with year, while the ‘share’ shows the difference. Therefore, to some extent the ‘view’ and ‘save’ can evaluate scientific influence of papers as a complement measurement of traditional citation analysis. For example, extending the author-based influence measurement to the reader’s range. And the ‘share’ of *PLoS* papers seemingly just reflects the attention/mention of user rather than the academic influence because it is transient and uncorrelated with the citation.

In addition, it’s necessary to discuss the influence factors of relationship between citation and altmetrics of open access papers in detail, such as time, user, discipline or subject, social media etc., and the quantity of the sample in this paper also limit the universality of conclusions. In future, we will make a further research for the evaluation of open access papers from different platforms, different disciplines and different periods etc.

Abstract

Despite tremendous involvement of bibliometrics in profiling technological landscapes and identifying emerging topics, how to predict potential technological change is still unclear. This paper proposes a bi-layer network analytics-based prediction method to characterize the potential of being emerging generic technologies. Initially, based on the innovation literature, three technological characteristics are defined, and quantified by topological indicators in network analytics; a link prediction approach is applied for reconstructing the network with weighted missing links, and such reconstruction will also result in the change of related technological characteristics; the comparison between the two ranking lists of terms can help identify potential emerging generic technologies. A case study on predicting emerging generic technologies in information science demonstrates the feasibility and reliability of the proposed method.

Introduction

An early definition of emerging generic technologies can be traced back to the early 1990s, highlighting technologies that enable revolutionary impacts on the economy and society (Martin, 1995), and Maine and Garnsey (2006) moved down on the line and specified the 'generic' nature as benefits on a wide range of sectors and the 'emerging' nature as the potential for innovation. Even though emerging generic technologies conceptually contain overlaps with emerging technologies (Rotolo et al., 2015), it is clear that, compared to technologies that hold disruptive powers to a given technological area – e.g., dye sensitized solar cells (Zhang, Zhou, et al., 2014), the exploitations and applications of emerging generic technologies would create values for fostering innovation in broad disciplines (Coccia, 2017) – e.g., nanotechnology (Maine & Thomas, 2017). During the past decades, investigations on how to measure the impacts of emerging generic technologies on accelerating the economic growth (Bresnahan & Trajtenberg, 1995; Crafts, 2004; Qiu & Cantwell, 2018) and how to transfer technological breakthroughs into impactful innovations (Appio et al., 2017; Sinfield & Solis, 2016) have been conducted in the innovation literature.

The engagement of bibliometrics on assisting in the management of technology has been well observed, e.g., profiling a given technological area (Chakraborty et al., 2015; Guo et al., 2010), identifying emerging topics in science and technology (Glänzel & Thijs, 2012; Small et al., 2014), and tracking the pathways of technological change (Hou et al., 2018; Zhang et al., 2016; Zhou et al., 2014). The use of advanced information technologies, e.g., topic models, streaming data analytics, and machine learning techniques, greatly strengthens the capability of traditional bibliometrics in handling large-scale data analytics (Ding & Chen, 2014; Klavans & Boyack, 2017), discovering hidden relationships (Zhang et al., 2018; Zhang et al., 2017), and visualizing complicated landscapes and structures (Börner et al., 2012; Suominen & Toivanen, 2016).

Even though it has been a long time since the use of network analytics in social science (Borgatti et al., 2009), network analytics was introduced to bibliometric studies in the late 2000s, which were initially used to investigate research collaborations and disciplinary interactions through analyzing bibliographic couplings (Yan et al., 2009; Yang et al., 2010). Its effective combination with citation networks has attracted great attentions on identifying emerging topics and evaluating research impacts (Takeda & Kajikawa, 2009; Yan, 2015). Such advantages have been applied for predicting emerging technologies (Érdi et al., 2013) and discovering technological opportunities (Park & Yoon, 2018). However, despite recognitions from the both communities, concerns are still raised, e.g., bibliometrics is insufficient on 'characterizing the potential of what is detected to be emerging' (Rotolo et al., 2015). Additionally, with the rapid development of natural language processing (NLP) techniques, co-word statistics provide a new angle for bibliometrics, but how to explore insights based on semantics retrieved from co-word-based networks is still elusive. Apparently, such insights are complementary with citation networks.

Aiming to address these concerns, this paper is to propose a bi-layer network analytics-based prediction method for characterizing the potential of being emerging generic technologies. Initially, we refer studies conducted by Maine and Garnsey (2006) and Rotolo et al. (2015), and consider emerging generic technologies as novel and fast-growing technologies with prominent impacts on a relative broad range of disciplines. A co-authorship network and a co-term network are constructed and integrated as a bi-layer network to represent the content of involved disciplines/technologies, and indicators for profiling the topological structure of networks are introduced to identify technological characteristics from three aspects – i.e., fundamentality, connectivity, and externality. Further, a link prediction approach is incorporated to calculate weights of all links (including missing links) in the both networks, and such reconstruction would be the key to capture a potential characteristic change of involved technologies. Thus, investigating such change could be the way of characterizing the potential of being emerging generic technologies. We then demonstrate the feasibility and reliability of the proposed method through a case study, which predicts emerging generic technologies in information science disciplines by analyzing 17,882 articles published in 15 selected journals and conference proceedings in the field between Jan 1, 2000 and Dec 31, 2016.

The rest of this paper is organized as follows: The Methodology section describes the details of the proposed bi-layer network analytics-based prediction method, and the Case Study section follows, presenting the data, results, and empirical insights derived from the case. We then conclude our study and outline potential future directions.

Methodology

The research framework of the proposed bi-layer network analytics-based prediction method for characterizing the potential of being emerging generic technologies is given in Fig. 1.

Technological characteristics

Following the studies conducted by Maine and Garnsey (2006) and Rotolo et al. (2015), we identify new technologies that can be fundamentally applied to a broad range disciplines, with capabilities of connecting diverse technological areas and adaptively transferring among enterprises, as emerging generic technologies, and the characteristics of emerging generic technologies are specifically defined from the following three perspectives:

- Fundamentality is to measure *whether this technology can be applied to a broad range of sectors, disciplines, or research areas*.

- Connectivity is to measure *whether this technology is sharing close relationships with other technologies in the same or different technological areas*.
- Externality is to measure *whether this technology is involved and can be transferred among diverse enterprises and research groups*.

Figure 1. Research framework of the bi-layer network analytics-based prediction method.

Bi-layer network analytics

A bi-layer network includes a co-term network and a co-authorship network. We denote $N = \{(V^t, E^t), (V^a, E^a), E^{at}\}$ as a bi-layer network, in which (V^t, E^t) and (V^a, E^a) are the sets of nodes and links in the co-term network and the co-authorship network respectively and E^{at} is the set of links between the two networks. A sample of a bi-layer network is given in Fig. 2.

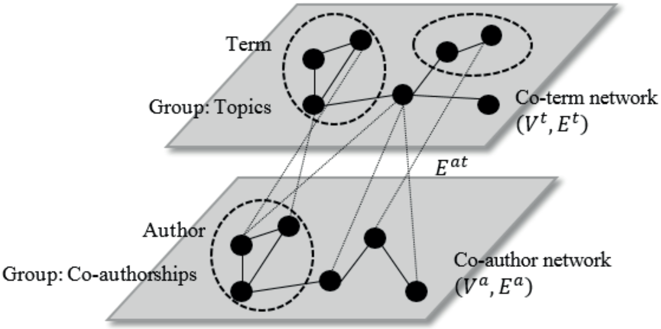

Figure 2. Sample of a bi-layer network.

Specifically, the co-term network is generated based on the co-occurrence statistics of terms derived from the title and abstract fields of collected records, and the co-authorship network is based on the statistics of co-authorship behaviors. The both networks are non-direct graphs, in which 1) each node represents either a term or an author and 2) each link represents the co-occurrence/co-authorship relationships between connected nodes and is weighted by the frequency of such co-occurrence/co-authorship. Significantly, the authorships of terms are used to be the links between the two layers – i.e., the co-term network and the co-authorship network.

When considering each term represents a technological component (e.g., materials, functions, manufacturing processes, and applications), we apply network analytics for investigating the topological structures of the bi-layer network to quantify the three characteristics of emerging generic technologies.

- Fundamentality

The fundamentality of a technology is to measure the breadth and depth of a technology's influence in given technological areas. In the co-term network, centrality, a traditional indicator of measuring network topological structures (Freeman, 1977, 1978), is exploited to quantify the value of the fundamentality. Since a number of centrality-based indicators have been developed for different emphases, three forms of centrality are involved in this study:

1) Degree Centrality – the degree of a node, reflecting the breadth of its potential influence. The degree centrality of node v_i^t in the co-term network can be calculated as follows:
$$DC(v_i^t) = \frac{\sum_{j=1}^{|V^t|} w_{v_i^t,v_j^t}}{|V^t| - 1}$$
where $|V^t|$ is the number of nodes in the co-term network and $w_{v_i^t,v_j^t}$ is the weight of the link between node v_i^t and node v_j^t.
2) Closeness Centrality – the closeness between a node and other nodes in the same network, reflecting its professionalism in a given area, that is, the depth of its potential influence. The closeness centrality of node v_i^t can be calculated as follows:
$$CC(v_i^t) = \frac{|V^t| - 1}{\sum_{j=1}^{|V^t|} d_{v_i^t,v_j^t}}$$
where $d_{v_i^t,v_j^t}$ is the shortest distance between node v_i^t and node v_j^t.
3) Between Centrality – the number of the shortest paths crossing a node, reflecting its role in a cross area, that is, its potential influence in a cross-disciplinary direction. The between centrality of node v_i^t can be calculated as follows:
$$BC(v_i^t) = \frac{2\sum \frac{\sigma(v_i^t)_{v_s^t,v_p^t}}{\sigma_{v_s^t,v_p^t}}}{(|V^t| - 1)(|V^t| - 2)}, v_i^t \neq v_s^t \neq v_p^t$$
where v_s^t and v_p^t are two different nodes in the network, $\sigma_{v_s^t,v_p^t}$ represents the number of the shortest paths between nodes v_s^t and v_p^t, and $\sigma(v_i^t)_{v_s^t,v_p^t}$ is the number of the shortest paths between nodes v_s^t and v_p^t, crossing node v_i^t.

The three forms of centrality exploit different topological structures – e.g., degree centrality concentrates on the number of neighbor nodes, closeness centrality highlights the capability of connecting other nodes, and between centrality emphasizes the importance of a node in the communication of a network. In other words, the three forms of centrality could cover the breadth and depth of a technology's influence in a given technological area, as well as its potential influence in a cross-disciplinary direction. Given the circumstances, we exploit the three for calculating the fundamentality of a technology, and we calculate the fundamentality of a node $F(v_i^t)$ as the average value of the three indicators.

- Connectivity

The connectivity of a technology is considered as its relationships with other technologies and technological groups, indicating its capability of involving diverse sectors, disciplines, and technological areas. In the co-term network, 1) initially, a smart local moving algorithm (Waltman & Van Eck, 2013) is applied for community detection – i.e., identifying technological groups G^t; and then, 2) we calculate the connectivity $C(v_i^t)$ between node v_i^t and its community as follows:

$$C(v_i^t) = \frac{\sum_{j=1}^{|G^t(v_i^t)|} w_{v_i^t,v_j^t}}{|G^t(v_i^t)|}$$

where $|G^t(v_i^t)|$ represents the number of nodes in the community to which node v_i^t belong.

- Externality

The externality of a technology takes both technologies and their owners into considerations – i.e., if a technology is owned by more than one owner (e.g., enterprises and research institutions) and can be easily transferred between those owners, or even between different sectors, we consider this technology is generic in the related fields. Thus, both the co-term network and the co-authorship network in a bi-layer network will be exploited for measuring the externality of a node $E(v_i^t)$ as follows:

$$L(v_m^a) = \sum_{n=1}^{|V^a|} w_{v_m^a,v_n^a}$$

$$E(v_i^t) = \sum_{n=1}^{|V^a|} w_{v_i^t,v_n^a} \times L(v_n^a)$$

where v_m^a is a node in the co-authorship network and $|V^a|$ is the number of nodes in the co-authorship network.

Despite some weighting approaches, e.g., entropy-based and standard deviation-based weights, we decide to use a 3D map to visualize values of the three technological characteristics, highlighting distinctive values based on diverse requirements and preferences.

Link prediction

A common neighbors (CN)-based link prediction approach (Newman, 2001) is exploited to weight all links (including missing links) in the bi-layer network, and such reconstruction of the network would represent possible connections between terms and potential collaborations between authors in future. The basic assumption of the CN-based approach is that if two unlinked nodes have many common neighbors, it is highly possible that a link will appear between the two nodes. Thus, the CN value of each link can be calculated as follows:

$$CN(v_x, v_y) = \sum_{z=1}^{|V(v_x,v_y)|} \left(w_{v_x,v_z} + w_{v_y,v_z}\right)$$

where v_x and v_y are two different and unlinked nodes in a bi-layer network (either the co-term network or the co-authorship network) and $|V(v_x, v_y)|$ is the set of nodes in the bi-layer network, which connect v_x and v_y.

The output of this link prediction approach is a ranking list of all links in the bi-layer network, including missing links in the current network. Thus, a predicted bi-layer network will be generated, reflecting potential technological change in the near future.

Identification of emerging generic technologies

According to the technological characteristics, a ranking list (List A) of technologies with emerging generic features will be generated based on a bi-layer network. With the exploitation of link prediction approaches, missing links in the bi-layer network will be created and existing links will be re-weighted, i.e., a predicted bi-layer network is constructed. Apparently, the change of the topological structure of the existing network will result in the change of the technological characteristics of related technologies, and thus, a new ranking list (List B) will be generated. Therefore, comparing the two lists respectively generated by the two bi-layer networks will help characterize the potential of being emerging generic technologies. Several selection criteria will be highlighted, including:

- A technology only appears in List B and with a high rank;
- Compared to List A, the rank of a technology in List B dramatically increase;
- A technology appears in the top rank of the both lists;

Case Study: What are emerging generic technologies in information science?

It would likely be arguable that information science can only represent an individual discipline and it is critical to identify emerging generic technologies from such one discipline rather than a broad range of disciplines. Our consideration here is that information science has been spearheading a cross-disciplinary direction that bridges fundamental studies (e.g., mathematics, physics, and computer science) with real-world needs raised in disciplines of social science. Therefore, it would be interesting to identify emerging generic technologies from such a cross-disciplinary area, which would originate from other disciplines but build up the foundations of information science and create extensive impacts on and out of the discipline. We followed the search strategy proposed by Hou et al. (2018) and selected 15 journals and conference proceedings, covering 17,445 records between January 1, 1996 and December 31, 2016.

Table 1. List of selected journals and conference proceedings

Journal Name	*Journal Name*
Annual Review of Information Science and Technology	Library Resources & Technical Services
Information Processing & Management	Program: Automated Library and Information Systems
Journal of the Association for Information Science and Technology	Information Research
Journal of Documentation	Journal of Informetrics
Journal of Information Science	Research Evaluation
Library & Information Science Research	The Electronic Library
ASIS&T Annual Meeting Proceedings	Information Technology and Libraries
Scientometrics	

Note that the table only lists the current names of selected journals and conference proceedings, but we fully considered their previous names when collecting data.

We combined the title and abstract fields of the 17,445 records and retrieved 213,031 terms by a natural language processing (NLP) function integrated in the VantagePoint[1]. A term clumping process (Zhang, Porter, et al., 2014) was applied for data cleaning by removing noise and consolidating synonyms, and the stepwise results are given in Table 2. The 25,359 terms were used for constructing the co-term network.

[1] VantagePoint is a software platform for bibliometrics-based text analytics and knowledge management, owned by Search Technology Inc. More details can be found at the website: www.vantagepoint.com.

Table 2. Stepwise results of term clumping

Step	*Description*	*#Terms*
0	Raw terms retrieved by the NLP technique;	213,031
1	Remove single-word terms, e.g., “information”;	189,111
2	Remove terms starting/ending with non-alphabetic characters, e.g., “step 1” and “1.5 m/s”;	180,209
3	Remove meaningless terms, e.g., pronouns, prepositions, and conjunctions;	175,488
4	Remove common terms in scientific articles, e.g., “research framework”;	157,041
5	Consolidate synonyms based on expert knowledge, e.g., “co-word analysis” and “word co-occurrence analysis”;	135,967
6	Consolidate terms with the same stem, e.g., “information system” and “information systems”	109,115
7	Remove terms appearing less than 3 times;	25,359

Note that: 1) Expert knowledge in Step 5 were mostly based on previous experiments and experiences; and 2) we usually remove terms appearing once in the dataset, but we decided to increase the threshold to keep the scale of terms at a relatively small level in Step 7.

Regarding to author names, we collected 5349 distinctive authors from a raw list of 18,882 authors, and the cleaning process includes: 1) a light author name disambiguation function integrated in the VantagePoint was applied to consolidate potential variations – e.g., “Eugene Garfield”, “Garfield, Eugene”, and “E Garfield”; and 2) authors who only published one paper in our dataset were removed. The co-authorship network was then constructed.

Thus, a bi-layer network was built up by connecting the co-term network and the co-authorship network with links, representing the authorships of terms and weighted by the frequency. a demonstration of the bi-layer network in VOSViewer (Waltman et al., 2010) is given in Fig. 3. Note that links between the co-term network and the co-authorship network are not given.

Network analytics were applied to quantify the three technological characteristics of the 25,359 terms, and the descriptive statistics of the results are given in Table 3. Based on the mean of the three characteristics, we selected 1000 terms and generated one 3D map in Fig. 4 (Left), visualizing and locating distinctive terms in a 3D solution.

Table 3. Descriptive statistics for technological characteristics.

No.	*Characteristics*	*Sub-characteristics*	*Max*	*Min*	*Mean*	*S.D.*
1	Fundamentality	Degree Centrality	1	0	0.014	0.023
		Closeness Centrality	1	0	0.690	0.068
		Between Centrality	1	0	0.001	0.008
		Average	1	0	0.235	0.028
2	Connectivity	N/A	7.47	0	0.050	0.220
3	Externality	N/A	20853	0	154.3	437.5

Note that regarding to fundamentality, we used the average of the three sub-characteristics as the value of fundamentality in further analytics.

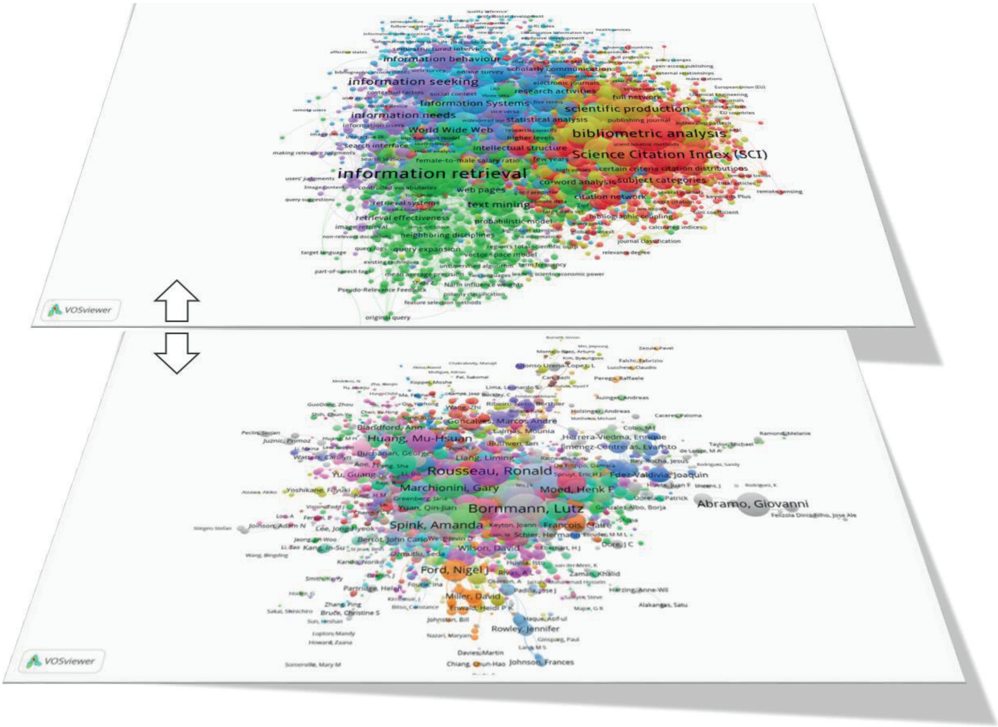

Figure 3. A bi-layer network for information science.

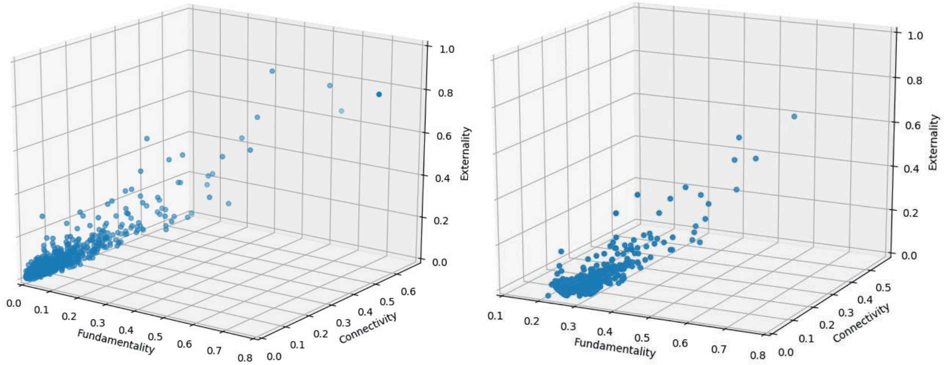

Figure 4. 3D map for 1000 terms with technological characteristics – Left for the current bi-layer network and Right for the predicted bi-layer network.

The common neighbor-based link prediction approach was then applied to calculate the CN values of all links, including missing links. With such values, the structure of the bi-layer network was changed and the technological characteristics of all nodes could be re-calculated. The descriptive statistics for technological characteristics in the predicted bi-layer network are given in Table 4, and a 3D map for visualizing selected 1000 terms with technological characteristics is given in Fig. 4 (Right).

Table 4. Descriptive statistics for technological characteristics in the predicted bi-layer network.

No.	*Characteristics*	*Sub-characteristics*	*Max*	*Min*	*Mean*	*S.D.*
1	Fundamentality	Degree Centrality	1	0	0.010	0.036
		Closeness Centrality	1	0	0.001	0.014
		Between Centrality	1	0	0.693	0.063
		Average	1	0	0.235	0.031
2	Connectivity	N/A	1	0	0.001	0.015
3	Externality	N/A	1	0	0.027	0.023

We exploited the receiver operating characteristic (ROC) analysis and the value of area under the curve (AUC) to validate the performance of the link prediction approach (Fawcett, 2006). Briefly, in the ROC analysis the applied dataset was randomly divided into a training set and a test set, then, the ranking list generated by the link prediction approach in the training set would be compared with the true ranking list in the test set, and an AUC value can be calculated. The AUC values for links in the co-term network, in the co-authorship network, and between the two networks are given in Fig. 5.

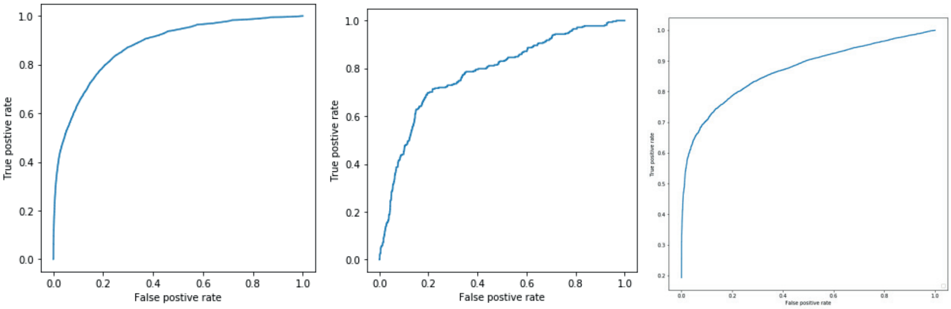

Figure 5. AUC values for validating the link prediction approach – Left for links in the co-term network, Middle for links in the co-authorship network, and Right for links between the both.

As shown in Fig. 5, AUC values for links in the co-term network, in the co-authorship network, and between the two networks are 0.89, 0.79, and 0.95 respectively, indicating an acceptable result of the link prediction approach.

We then compared the difference between the two ranking lists (i.e., the ones generated by the bi-layer network and the predicted bi-layer network respectively) and picked up a list of terms (given in Table 5) whose ranking is within the Top 50 in the one generated by the predicted bi-layer network but largely different from the previous one, indicating its potential of being emerging generic technologies in information science.

Table 5. Selected terms indicating the potential of being emerging generic technologies

No.	*Terms*	*Rank Change*	*No.*	*Terms*	*Rank Change*
1	Information retrieval	63 - 1	6	Text mining	383 - 24
2	Information seeking	15 - 4	7	Social network analysis	52 - 28
3	Digital libraries	23 - 9	8	Science policy	54 - 36
4	Information systems	45 - 17	9	Co-authorship network	79 - 43
5	H index	169 - 22			

Note that compared to emerging generic "technologies", we would prefer to extend this concept and consider these selected terms as emerging generic "research topics" to highlight their emphasis on scientific research.

Terms appearing in Table 5 are coherent with the study conducted by Zhang et al. (2018), where several key topics in bibliometrics were identified. Several insights are summarized below:

- As a fundamental toolkit, the involvement of *information retrieval* (e.g., *text mining*) and *information systems* techniques has significantly changed the information science discipline, but with the rapid development of information technologies, especially artificial intelligence, the involvement would be further enhanced and become an emergent direction in information science.
- *Information seeking* and *digital libraries* would be considered as two mainstream tasks of information science and library science, and the boom of social media would become a key to dramatically extend its current research areas and generate new topics.
- *Social network analysis* and *co-authorship network* are the applications of complex network analytics for analyzing science maps, which could be a cross-disciplinary direction and have attracted great attention in the past decades.
- *H index* is a traditional indicator for research evaluation in bibliometrics and could be considered as the application of complex network analytics as well. How to modify h index to evaluate researchers and research institutions from comprehensive aspects is still a hot topic in bibliometrics.
- *Science policy* could be a practical area of information science (e.g., bibliometrics). Even though such applications have appeared in the literature for decades, new problems in the area of science, technology, and innovation policy (STIP), and new solutions for existing STIP problems are still challenging researchers in information science.

Conclusions and Future Studies

This paper provides a bi-layer network analytics-based prediction method for characterizing the potential of being emerging generic technologies, in which 1) three technological characteristics are identified and then quantified by topological indicator, and 2) a common neighbor-based link prediction approach is applied for reconstructing networks with weighted missing links. Comparison between the ranking lists of terms indicating the potential of being emerging generic technologies, which are respectively generated by the current and the reconstructed networks, is used to identify potential emerging generic technologies. A case study on predicting emerging generic technologies in information science demonstrates the feasibility and reliability of the proposed method.

Future directions can be conducted to address limitations of this study from the following aspects: 1) it would be crucial to build up the conceptual foundation of this study in our further studies, which might provide solid theoretical support for the proposed method; 2) a modified link prediction approach can be developed to better adapt to a bi-layer network, and comparisons with baselines can be applied as well; 3) it is more convincing to quantitatively or qualitatively validate the results based on different indicators and with diverse practical needs; and 4) examining the proposed method in cases with relatively broad disciplines would further help demonstrate its reliability.

Crowdsourcing open citations with CROCI
An analysis of the current status of open citations, and a proposal

Abstract

In this paper, we analyse the current availability of open citations data in one particular dataset, namely COCI (the OpenCitations Index of Crossref open DOI-to-DOI citations; http://opencitations.net/index/coci) provided by OpenCitations. The results of these analyses show a persistent gap in the coverage of the currently available open citation data. In order to address this specific issue, we propose a strategy whereby the community (e.g. scholars and publishers) can directly involve themselves in crowdsourcing open citations, by uploading their citation data via the OpenCitations infrastructure into our new index, CROCI, the Crowdsourced Open Citations Index.

Introduction

The availability of open scholarly citations – i.e. citation data that are *structured*, *separate*, *open*, *identifiable* and *available* (Peroni and Shotton, 2018) – is a public good, which is of intrinsic value to the academic world as a whole (Shotton, 2013; Peroni et al. 2015; Shotton, 2018), and is particularly crucial for the scientometrics and informetrics community, since it supports reproducibility (Sugimoto et al., 2017) and enables fairness in research by removing such citation data from behind commercial paywalls(Schiermeier, 2017). Despite the positive early outcome of the Initiative for Open Citations (I4OC, https://i4oc.org/), namely that almost all major scholarly publishers now release their publication reference lists, with the result that more than 500 million citations are now open via the Crossref API (https://api.crossref.org), and despite the related ongoing efforts of sister infrastructures and initiatives such as OpenCitations (http://opencitations.net) and WikiCite/Wikidata (https://www.wikidata.org), many scholarly citations are not freely available. While these initiatives have the potential to disrupt the traditional landscape of citation availability, which for the past half-century has been dominated by commercial interests, the present incomplete coverage of open citation data is one of the most significant impediments to open scholarship (van Eck et al., 2018).
In this work, we analyse the current availability of open citations data within one particular dataset, namely COCI (the OpenCitations Index of Crossref open DOI-to-DOI citations; http://opencitations.net/index/coci). This dataset is provided by OpenCitations (Peroni et al., 2015), a scholarly infrastructure organization dedicated to open scholarship and the publication of open bibliographic and citation data by the use of Semantic Web (Linked Data) technologies. Launched in July 2018, COCI is the first of the Indexes proposed by OpenCitations (http://opencitations.net/index) in which citations are exposed as first-class data entities with accompanying properties. It has already seen widespread usage (over nine hundred thousands API calls since launch, with half of these in January 2019), and has been adopted by external services such as VOSviewer (van Eck and Waltman, 2010).
In particular, in this paper we address the following research questions (RQs):

1. What is the ratio between open citations vs. closed citations within each category of scholarly entities included in COCI (i.e. journals, books, proceedings, datasets, and others)?

2. Which are the top twenty publishers in terms of the number of open citations received by their own publications, according to the citation data available in COCI?
3. To what degree are the publishers highlighted in the previous analysis themselves contributing to the open citations movement, according to the data available in Crossref?

The results of these analyses show a persistent gap in the coverage of the currently available open citation data. To address this specific issue, we have developed a novel strategy whereby members of the community of scholars, authors, editors and publishers can directly involve themselves in crowdsourcing open citations, by uploading their citation data via the OpenCitations infrastructure into our new index, **CROCI, the Crowdsourced Open Citations Index**.

Methods and material

To answer the RQs mentioned above, we used open data and technologies coming from various parties. Specifically, the open CC0 citation data we used came from the CSV dump of most recent release of COCI dated 12 November 2018 (OpenCitations, 2018), which contains 449,840,503 DOI-to-DOI citation links between 46,534,705 distinct bibliographic entities. The Crossref dump we used for the production of this most recent version of COCI was dated 3 October 2018, and included all the Crossref citation data available at that time in both the 'open' dataset (accessible by all) and the 'limited' dataset (accessible only to users of the Crossref Cited-by service and to Metadata Plus members of Crossref, of which OpenCitations is one – for details, see https://www.crossref.org/reference-distribution/).

We additionally extracted information about the number of closed citations to each of the 99,444,883 DOI-identified entities available in the October 2018 Crossref dump. This number was calculated by subtracting the number of open citations to each entity available within COCI from the value "is-referenced-by-count" available in the Crossref metadata for that particular cited entity, which reports all the DOI-to-DOI citation links that point to the cited entity from within the whole Crossref database (including those present in the Crossref 'closed' dataset).

Furthermore, we extracted the particular publication type of each entity, so as to identify it either as a journal article, or as a book chapter, etc. We determined these publication types for all the DOI-identified entities available in the Crossref dump we used. We then identified the publisher of each entity, by querying the Crossref API using the entity's DOI prefix. This allowed us to group the number of open citations and closed citations to the articles published by that particular publisher, and to determine the top twenty publishers in terms of the number of open citations that their own publications had received.

Finally, we again queried the Crossref API, this time using the DOI prefixes of the *citing* entities, to check the participation of these top twenty publishers in terms of the number of open citations they were themselves publishing in response to the open citation movement sponsored by I4OC. Details of all these analyses are available online in CC0 (Heibi et al., 2019).

Results

First (RQ1) we determined the numbers of open citations and closed citations received by the entities in the Crossref dump. All the entity types retrieved from Crossref were aligned to one of following five categories: journal, book, proceedings, dataset, other – the mapping between Crossref types and the five types we used in our analysis is illustrated in the description of the table "croci_types.csv" in (Heibi et al., 2019). The outcomes are summarised in Figure 1, where it is evident that the number of open citations available in COCI is always greater than the number of closed citations to these entities within the Crossref database to which COCI does not have access, for each of the publication categories considered, with the categories *proceedings* and *dataset* having the largest ratios.

Analysis of the Crossref data show that there are in total ~4.1 million DOIs that have received no open citations and at least one closed citation. Conversely, there are ~10.7 million DOIs that have received no closed citations and at least one open citation in COCI. Most of the papers in both these categories have received very few citations.

The outcome of the second analysis (RQ2) shows which publishers are receiving the most open citations. To this end, we considered all the open citations recorded in COCI, and compared them with the number of closed citations to these same entities recorded in Crossref. Figure 2 shows the top twenty publishers that received the greatest number of open citations. Elsevier is the first publisher according to this ranking, but it also records the highest number of closed citations received (~97M vs. ~105.5M). The highest ratio in terms of open citations vs. closed citations was recorded by IEEE publications (ratio 6.25 to 1), while the lowest ratio was for the American Chemical Society (ratio 0.73 to 1).

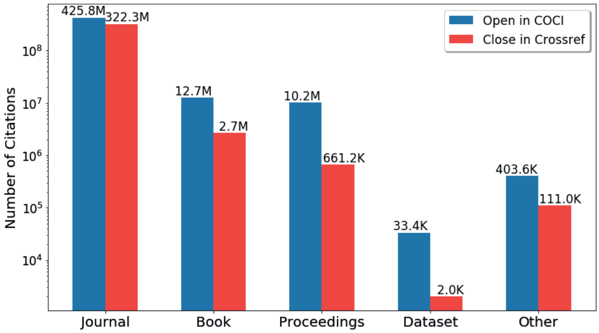

Figure 1. The number of open citations (available in COCI) vs. closed citations (according to Crossref data) received by the cited entities within COCI, analyzed and grouped according to five distinct categories. [Note that the vertical axis has a logarithmic scale].

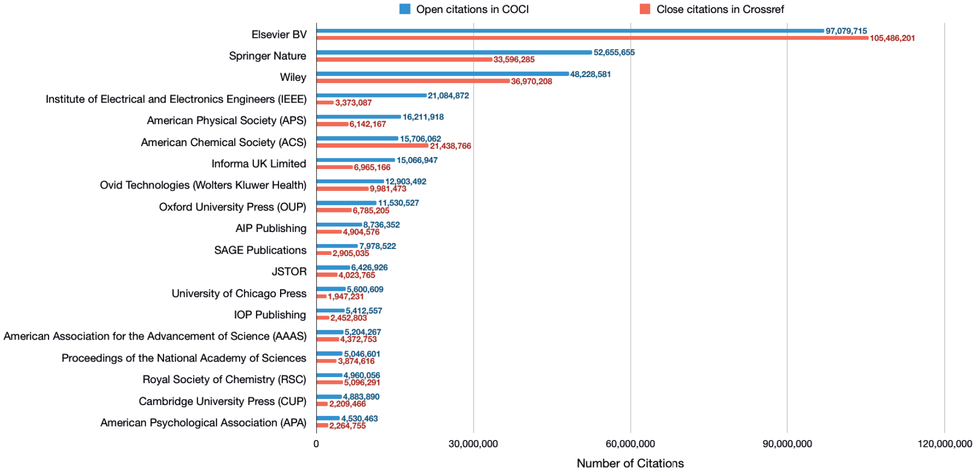

Figure 2. The top twenty publishers sorted in decreasing order according to the number of open citations the entities they published have received, according to the open citation data within COCI. We accompany this count with the number of closed citations to the entities published by each of them according to the values available in Crossref.

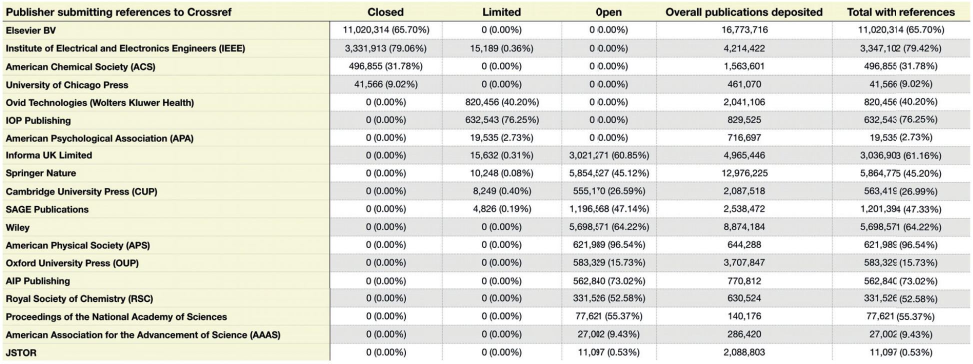
Considering the twenty publishers listed in Figure 2, we wanted additionally to know their current support for the open citation movement (RQ3). The results of this analysis (made by querying the Crossref API on 24 January 2019) are shown in Figure 3. Among the top ten publishers shown in Figure 2, i.e. those who themselves received the largest numbers of open citations, only five, namely Springer Nature, Wiley, the American Physical Society, Informa UK Limited, and Oxford University Press, are participating actively in the open publication of their own citations through Crossref.

It is noteworthy that JSTOR contributes very few references to Crossref, while the many citations directed towards its own holdings place JSTOR twelfth in the list of publishers receiving open citations (Figure 2). However, as the last column of Figure 3 shows, *all* the major publishers listed here are failing to submit reference lists to Crossref for a large number of the publications for which they submit metadata, that number being the difference between the value in the last column for that publisher and the combined values in the preceding three columns. JSTOR is the worst in this regard, submitting references with only 0.53% of its deposits to Crossref, while the American Physical Society is the best, submitting references with 96.54% of its publications recorded in Crossref.

Additional information about these analyses, including the code and the data we have used to compute all the figures, is available as a Jupyter notebook at https://github.com/sosgang/pushing-open-citations-issi2019/blob/master/script/croci_nb.ipynb.



Publisher submitting references to Crossref	Closed	Limited	Open	Overall publications deposited	Total with references

Figure 3. The contributions to open citations made by the twenty publishers listed in Figure 2, as of 24 January 2018, according to the data available through the Crossref API. The counts listed in the first three results columns of this table refers to the number of publications for which each publisher has submitted metadata to Crossref that include the publication's reference list, the categories *closed*, *limited* and *open* referring to publications for which the reference lists are not visible to anyone outside the Crossref Cited-by membership, are visible only to them and to Crossref Metadata Plus members, or are visible to all, respectively. Additional information on this classification of Crossref reference lists is available at https://www.crossref.org/reference-distribution/. The fourth results column in the table shows the total number of publications for which the publisher has submitted metadata to Crossref, whether or not those metadata include the reference lists of those publications, and the fifth results column shows the total number of publications for which the publisher *has* submitted the reference list with the other metadata. The percentage values given in parentheses show the percentage of publications in each category whose metadata submitted to Crossref includes the reference lists, these percentages being obtained by dividing the values in each column by the total number of publications for which that publisher has submitted metadata to Crossref shown in the fourth results column.

It should be stressed that a very large number of potentially open citations are totally missing from the Crossref database, and consequently from COCI, for the simple reason that many publishers, particularly smaller ones with limited technical and financial resources, but also all the large ones shown in Figure 3 and most of the others, are simply not depositing with Crossref the reference lists for any or all of their publications.

Discussion

According to the data retrieved, the open DOI-to-DOI citations available in COCI exceed the number of closed DOI-to-DOI citations recorded in Crossref for every publication category, as shown in Figure 1. The journal category is the one receiving the most open citations overall, as expected considering the historical and present importance of journals in most areas of the scholarly ecosystem. However, the number of closed citations to journal articles within Crossref is also of great significance, since these 322 million closed citations represent 43% of the total.

It is important to note that about one third of these closed citations to journal articles (according to Figure 2) are references to entities published by Elsevier, and that references from within Elsevier's own publications constitute the largest proportion of these closed citations, since Elsevier is the largest publisher of journal articles. Thus, Elsevier's present refusal to open its article references is contributing significantly to the invisibility of Elsevier's own publications within the corpus of open citation data that is being increasingly used by the scholarly community for discovery, citation network visualization and bibliometric analysis.

It is also worth mentioning the discrepancy between the citations available in COCI, which comes from the data contained in the open and limited Crossref datasets as of 3 October 2018, and those available within those same Crossref datasets as of 24 January 2019. The most significant difference relates to IEEE. While the citations present in COCI include those from IEEE publications to other entities prior to November 2018 (since in October 2018 its article metadata with references were present within the Crossref *limited* dataset), in November 2019 this scholarly society decided to close the main part of its Crossref references, and thus from that moment they became unavailable to Crossref Metadata Plus members such as OpenCitations, as highlighted in Figure 3. Thus, IEEE citations from articles whose metadata was submitted to Crossref after the date of this switch to *closed* can no longer be automatically ingested into COCI.

To date, the majority of the citations present in Crossref that are not available in COCI comes from just three publishers: Elsevier, the American Chemical Society and University of Chicago Press (Figure 3). In fact, considering the average value of 18.6 DOI-to-DOI citation links for each citing entity – calculated by dividing the total number of citations in COCI by the number of citing entities in the same dataset – these three publishers are holding more than 214 million DOI-to-DOI citations that could potentially be opened. (The IEEE citation data which was in the Crossref 'limited' category as of October 2018 are actually included in COCI, although those from that organization's more recent publications will no longer be, as mentioned above).

We think it is deeply regrettable and almost incomprehensible that any professional organization, learned society or university press, whose primary mission is to serve the interests of the practitioners, scholars and readers it represents, should choose *not* open all its publications' reference lists as a public good, whatever secondary added-value services it chooses to build on top of the citations that those reference lists contain.

CROCI, the Crowdsourced Open Citations Index

The results of the Initiative for Open Citations (I4OC) have been remarkable, since its efforts have led to the liberation of millions of citations in a relatively short time. However, many more citations, the lifeblood of the scholarly communication, are still not available to the general public, as mentioned in the previous section. Some researchers and journal editors, in particular, have recently started to interact with publishers that are not participating in I4OC, in attempts to convince them to release their citation data. Remarkable examples of these activities are the petition promoted by Egon Willighagen (https://tinyurl.com/acs-petition) addressed to the American Chemical Society, and the several unsuccessful requests made to Elsevier by the Editorial Board of the Journal of Informetrics, which eventually resulted in the resignation of the entire Editorial Board on 10 January 2019 in response to Elsevier's refusal to address their issues (http://www.issi-society.org/media/1380/resignation_final.pdf).

To provide a pragmatic alternative that would permit the harvesting of currently closed citations, so that they could then be made available to the public, we at OpenCitations have created a new OpenCitations Index: **CROCI, the Crowdsourced Open Citations Index**, into which individuals identified by ORCiD identifiers may deposit citation information that they have a legal right to submit, and within which these submitted citation data will be published under a CC0 public domain waiver to emphasize and ensure their openness for every kind of reuse without limitation. Since citations are statements of fact about relationships between publications (resembling statements of fact about marriages between individual persons), they are not subject to copyright, although their specific textual arrangements within the reference lists of particular publications may be. Thus, the citations from which the reference list of an author's publication has been composed may legally be submitted to CROCI, although the formatted reference list cannot be. Similarly, citations extracted from within an individual's electronic reference management system and presented in the requested format may be legally submitted to CROCI, irrespective of the original sources of these citations.

To populate CROCI, we ask researchers, authors, editors and publishers to provide us with their citation data organised in a simple four-column CSV file ("citing_id", "citing_publication_date", "cited_id", "cited_publication_date"), where each row depicts a citation from the citing entity ("citing_id", giving the DOI of the cited entity) published on a certain date ("citing_publication_date", with the date value expressed in ISO format "yyyy-mm-dd"), to the cited entity ("cited_id", giving the DOI of the cited entity) published on a certain date ("cited_publication_date", again with the date value expressed in ISO format "yyyy-mm-dd"). The submitted dataset may contain an individual citation, groups of citations (for example those derived from the reference lists of one or more publications on a particular topic), or entire citation collections. Should any of the submitted citations be already present within CROCI, **these duplicates will be automatically detected and ignored**.

The date information given for each citation should be as complete as possible, and minimally should be the publication years of the citing and cited entities. However, if such date information is unavailable, we will try to retrieve it automatically using OpenCitations technologies already available. DOIs may be expressed in any of a variety of valid alternative formats, e.g. "https://doi.org/10.1038/502295a", "http://dx.doi.org/10.1038/502295a", "doi: 10.1038/502295a", "doi:10.1038/502295a", or simply "10.1038/502295a".

An example of such a CVS citations file can be found at https://github.com/opencitations/croci/blob/master/example.csv. As an alternative to submissions in CSV format, contributors can submit the same citation data using the Scholix format (Burton et al., 2017) – an example of such format can be found at https://github.com/opencitations/croci/blob/master/example.scholix.

Submission of such a citation dataset in CSV or Scholix format should be made as a file upload either to Figshare (https://figshare.com) or to Zenodo (https://zenodo.org). For provenance purposes, the ORCID personal identifier of the submitter of these citation data should be explicitly provided in the metadata or in the description of the Figshare/Zenodo object. Once such a citation data file upload has been made, the submitter should inform OpenCitations of this fact by adding an new issue to the GitHub issue tracker of the CROCI repository at https://github.com/opencitations/croci/issues.

OpenCitations will then process each submitted citation dataset and ingest the new citation information into CROCI. These CROCI citations will be made available at http://opencitations.net/index/croci using a REST API and a SPARQL endpoint, and will additionally be published periodically as data dumps in Figshare, all releases being under CC0 waivers. We propose in future to enable combined searches over all the OpenCitations indexes, including COCI and CROCI.

We are confident that the community will respond positively to this proposal of a simple method by which the number of open citations available to the academic community can be increased, in particular since the data files to be uploaded have a very simple structure and thus should be easy to prepare. In particular, we hope for submissions of citations from within the reference lists of authors' green OA versions of papers published by Elsevier, IEEE, ACS and UCP, and from publishers not already submitting publication metadata to Crossref, so as to address existing gaps in open citations availability. We look forward to your active engagement in this initiative to further increase the availability of open scholarly citations.

Merits and Limits: Applying open data to monitor open access publications in bibliometric databases

Abstract

Identifying and monitoring Open Access (OA) publications might seem a trivial task while practical efforts prove otherwise. Contradictory information arise often depending on metadata employed. We strive to assign OA status to publications in Web of Science (WOS) and Scopus while complementing it with different sources of OA information to resolve contradicting cases. We linked publications from WOS and Scopus via DOIs and ISSNs to Unpaywall, Crossref, DOAJ and ROAD. Only about 70% of articles and reviews from WOS and Scopus could be matched via a DOI to Unpaywall. Matching with Crossref brought 53 distinct licences, which define in many cases the legally binding access status of publications. But only 53% of publications hold only a single licence on Crossref, while more than 42% have no licence information submitted to Crossref. Contrasting OA information from Crossref licences with Unpaywall we found contradictory cases overall amounting to more than 13%, which might be partially explained by (ex-)including green OA. A further manual check found about 17% of OA publications that are *not accessible* and about 15% non-OA publications that are *accessible* through publishers' websites. These preliminary results suggest that identification of OA state of publications denotes a difficult and currently unfulfilled task.

Introduction

Open access (henceforth OA) in scholarly communication describes unrestricted access to published peer-reviewed documents written by and addressed to researchers. These documents have traditionally been disseminated via publications in scientific journals, which charge for access to the respective content. Stimulated by a call for greater openness and transparency in general ("open science"), the OA movement has nowadays been accepted as one, though not the only, alternative for the dissemination of scholarly documents. Even publishers seem to embrace this new model as providing a suitable infrastructure while at the same time securing their own economic interests.

This inter-mixture of interests has resulted not only in one, but several forms of OA publications such as Gold, Hidden Gold, Hybrid, Green, Delayed, Bronze and Black which are mainly based on right to access and pay to publish models depending on venues where the OA publication is accessible.

Due to the individual ascription of single publications to one or several of these categories and the decentralized structure of the scientific publishing market with a variety of diverse publishers, the identification of OA is less trivial than it might seem. Even large bibliometric data provider rely on external information to provide information on OA[1] and most large scale undertakings by the scientometric community to obtain reliable information on OA prevalence rely on the use of web crawlers (Archambault et al., 2013; Piwowar et al., 2018)

Inspired by the Hybrid OA Dashboard (Jahn, 2017) we applied licensing information detailing the legally binding access state supplied by publishers to the publisher association Crossref to identify OA publications. We determined the OA status of all publications retrieved from Web of Science (henceforth WOS) and Scopus in-house databases of 2017 by confronting them to two sources of OA information, i.e., Unpaywall and Crossref. In Section 2, we present our data and methods. In Section 3 we present our findings, while we discuss our main results in Section 4.

[1] https://clarivate.com/blog/easing-access-to-open-access-clarivate-analytics-partners-with-impactstory/

Data & Method

We queried all publications from Scopus and WOS in in-house databases of 2017. Data included article's unique ID from database and DOI. We matched those DOIs with Unpaywall database from April 18th 2018 to determine the OA status for each single publication. In parallel, we matched those DOIs with Crossref data (using snapshot of the data from April 2018 based on plus service described in Crossref (2018)) and retrieved the available information on the licences of publications[2].

Additionally, we used the journals' ISSNs provided by Wohlgemuth, Rimmert, & Winterhager (2016) (and the updated version in Rimmert, Bruns, Lenke, & Taubert (2017)) to identify Gold OA publications. They use different known OA indexes (e.g., DOAJ[3] (Directory of Open Access Journals) and ROAD[4] (Directory of Open Access scholarly Resources) and determine if the respective ISSN is listed in those databases. They differentiate between ISSN and ISSNL which is more fine-grained by adding a specific ISSN to some special issues. We tried both ISSN and ISSNL, since the latter had higher matching records, therefore in our analysis presented in the Results section we use the ISSNL.

It is necessary to note that some publications had multiple licence URLs in Crossref database, we followed a procedure with four steps to ensure using only one licence per publication (see Table 2 for the frequencies of these publications):

1. If a publication had only one record in Crossref database, whether it had an *OA*, *non-OA*, *unclear* licence or *no licence information (i.e. NA)*, we used this status and categorized the publication as a unique one.
2. If a publication had multiple *OA* licence URLs, we removed the duplicates and categorized it as *OA*.
3. If a publication had a mixture of *OA* and *non-OA* licence URLs, we removed the duplicates and categorized it as *OA*.
4. If a publication had multiple *non-OA* licence URLs, we removed the duplicates and categorized it as *non-OA*.

A research assistant controlled the unique licences (a total of 56) we extracted from Crossref with available information online to categorize them as *OA* and *non-OA*. We used this categorization in parallel to established OA identification procedures (e.g., searching for journal's ISSN in DOAJ and ROAD in Gold OA identification) to ensure a higher level of robustness in our results.

In OA Identification process and in order to determine if a publication was OA or not, we applied a multi-category view separating Gold, Hidden Gold, Hybrid and Delayed OA, while doing so, we reached a new category of Probable Hybrid OA. Our investigation strategy for each category was as follows:

- **Gold OA**: As described earlier, we used the ISSNs provided by Rimmert et al. (2017) to determine Gold OA. We matched the respective ISSN (from both WOS and Scopus) with DOAJ and ROAD. If the respective ISSN was listed in one of those directories, the publication is categorized as *Gold OA*. We confronted Gold OA from DOAJ and ROAD with our research assistant's categorization of Crossref licences after the manual check of unique licence URLs.
- **Hidden Gold OA**: we used metadata from WOS and Scopus to determine the journal issue and looking at the licences of all publications in a single issue, if all publications had *OA*

[2] It is neccessary to note that our effort to send large number of requests to Crossref API (even while using plus service and through both rcrossref package in R and more fine-grained httr requests directly to Crossref API) faced timeout and response time errors and alternatively we chose to use the in-house snapshot of the Crossref data to circumvent the above error. This meant parsing large corpus of JSON files which can be time consuming depending on the goals of the analysis. Any effort on automating the proposed OA identification procedure needs to overcome the technical issues like this.

[3] https://doaj.org/

[4] https://road.issn.org/

licences, but the ISSN was not indexed in DOAJ or ROAD we categorized it as *Hidden Gold OA*.

- **Hybrid OA**: If an issue had at least one *non-OA* publication while having one or more *OA* publications, we categorized the OA publications as *Hybrid OA*.
- **Probable Hybrid OA**: If an issue did not have a *non-OA* publication while having one or more *OA* publications and some publications in the issue didn't have licence information, we categorized them as *Probable Hybrid OA*.
- **Delayed OA**: In all of the above cases, we looked into delays based on Crossref metadata (a difference in terms of days from day of publication and the date licence was assigned to the publication as described in CrossRef-API (2019), this is the time period known as *embargo time*) to determine if they were *Delayed*, therefore each of the above categories were split to two groups, *delayed* and *not-delayed*. If a publication had multiple licence URLs on Crossref, we controlled their respective delay times, if any of those were *not-delayed* we categorized the publication as such, while if any of the licences were *delayed*, the publication is identified as a *delayed* one.
- **Closed Access**: Strictly speaking, if the number of publications in an issue was equal to the number of *non-OA* publications and the ISSN was not indexed in DOAJ or ROAD, we categorized them as *Closed Access*.
- **NA (Not available)**: A publication that was not fitting in any of the above categories or did not have a licence URL to determine its condition was categorised as *NA*. Number of NAs are higher than *Closed Access* publications, since we aimed to keep the definitions as strict as possible.

Results

We present the results in two main sections, one regarding *Unpaywall* and the other on licences extracted from *Crossref*. We then present the *comparison between Unpaywall and Crossref* and the results of our *manual checks on random samples* for robustness of the results.

Table 1 shows the number of articles and review papers from WOS and Scopus with an equivalent record in Unpaywall database. It presents also the total number of articles and review papers in WOS/Scopus to provide a baseline for comparison. Unpaywall has close to 70% coverage in both cases while coverage of WOS is slightly higher (can be due to different indexing philosophy or DOIs completeness). In the following tables (in Unpaywall results), publications are limited to only articles and review papers published in 2000-2017.

Table 1: All articles and reviews from WOS (2000-2016) and Scopus (2000-2016) that could be matched to Unpaywall database via DOIs

Data Source	Frequency	Percent
WOS (Unpaywall match)	13,875,946	69.75%
WOS (total)	19,894,531	•
Scopus (Unpaywall match)	17,820,375	68.67%
Scopus (total)	25,951,839	•

Figure 1 presents the distribution of journals and publications indexed in WOS (top) and Scopus (bottom) matched with Unpaywall database and crosschecked the ISSNs with DOAJ. *Missing on DOAJ* in these Figures refer to those journals whose ISSN was missing from Rimmert et al. (2017) data, therefore we could not check if the ISSN is listed in DOAJ or not while *Others* means the ISSN was existing in Rimmert et al. (2017) but it was not listed as *OA* in DOAJ. Share of publications which don't have a matching ISSN in DOAJ (meaning they are not Gold OA) and are identified as OA in Unpaywall is interesting on both Figures (designated with “Missing on DOAJ | Unpaywall OA” as label). They could be other OA types (green, hybrid, hidden gold).

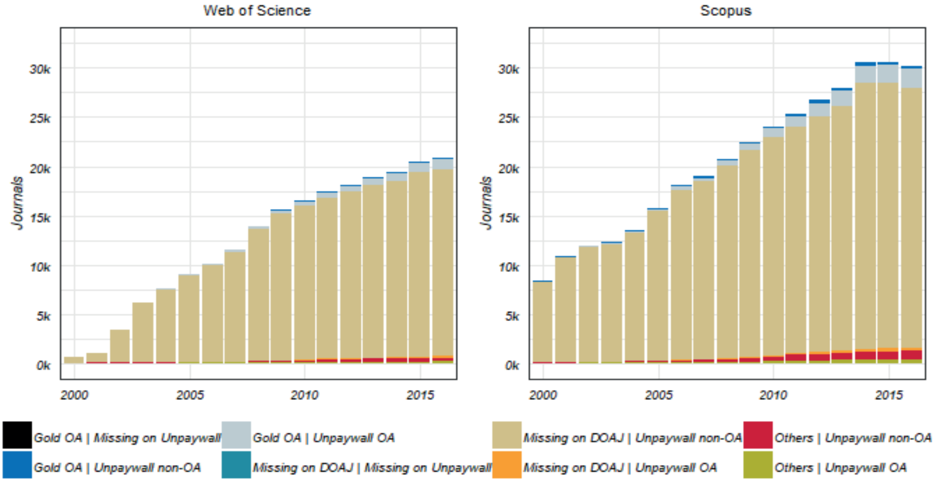

Figure 1: Journals indexed in WOS and Scopus matched with Unpaywall database and crosschecked the ISSNs with DOAJ (Gold OA) between 2000 and 2016

We matched publications to Crossref data from April 2018 and found 56 distinct licence types for all of the publications. Table 2 presents a descriptive view on whether publications have licence information recorded in Crossref. It shows that about 43% of publications from WOS or Scopus with a matching DOI indexed in Crossref do not have a licence URL. Some of the publications had more than one licence information in Crossref (as an example, the number of DOIs that each have 6 licence records on Crossref are 1,152). In case of multiple licences, if a publication had at least one OA licence, we categorized it as OA.

Table 2: Number of licences per DOI found in Crossref for articles and reviews indexed in either WOS, Scopus or both between 2000 and 2016

Number of licences per DOI	Frequency of DOIs	Percent
0	6,571,079	42.74
1	8,143,752	52.97
2	655,729	4.26
3	3,472	0.02
4	17	0.00
6	1,152	0.01

Figure 2 present the Gold, Hidden Gold, Hybrid and Delayed OA status of the publications from WOS (top) and Scopus (bottom), which is presented as trends over the years. We limited the years to 2000-2017 to show the most recent trends. To make these Figures more readable, we removed NA (those without a matching DOI or without a licence information on Crossref).

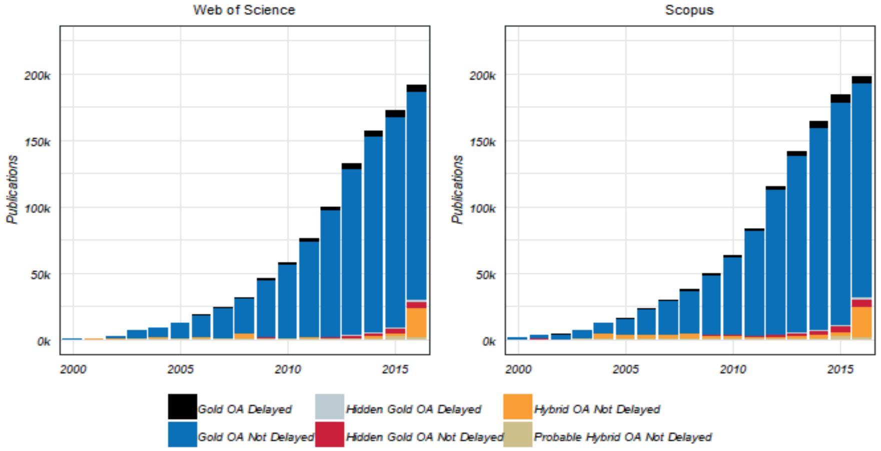

Figure 2: Count of gold and hybrid OA publications between 2000 and 2016 based on Crossref licence information, DOAJ and ROAD)

Tables 3 and 4 present the OA status comparison between Unpaywall and Crossref in WOS and Scopus publications, respectively. Note, Crossref OA status in the Tables is the categorization we developed using respective licence URLs. We double checked the contradictory cases and improved our while-list of OA licences, while some of the contradictions still remain (e.g., Unpaywall declares those publications as OA while they are closed access or vice versa, in case of licences on Crossref that are open access while the publication is declared as non-OA on Unpaywall). Overall contradictory cases amount to 22.98 % in WOS and 22.91% in Scopus which might partly be explained by the wider scope of Unpaywall including also green OA publications that might not be identified via license information only.

Table 3: OA status comparison between Unpaywall and Crossref on WOS publications

Crossref OA Status	Unpaywall OA Status	Frequency	Percent
Closed Access	Closed Access	4,767,019	35.26
NA	Closed Access	4,395,218	32.51
NA	Open Access	2,168,747	16.04
Closed Access	Open Access	1,649,674	12.20
Open Access	Open Access	438,100	3.24
Open Access	Closed Access	99,062	0.73
NA	NA	20	0.00
Closed Access	NA	10	0.00

Table 4: OA status comparison between Unpaywall and Crossref on Scopus publications

Crossref OA Status	Unpaywall OA Status	Frequency	Percent
Closed Access	Closed Access	5,890,312	40.75
NA	Closed Access	4,055,736	28.06
NA	Open Access	1,991,393	13.78
Closed Access	Open Access	1,879,773	13.01
Open Access	Open Access	506,106	3.50
Open Access	Closed Access	130,398	0.90
Open Access	NA	4	0.00
Closed Access	NA	1	0.00

Tables 5 and 6 present the result of our research assistant’s manual check for accessibility to article’s PDF file from publishers websites compared to the respective licence in Crossref and the OA status we manually assigned to those URLs in contrast to OA status from Unpaywall. It is interesting to see there are publications defined as Non-OA while their PDF is accessible from the publisher (14.42% in WOS and 14.54% in Scopus) or vice versa, OA publications (based on either Unpaywall, Crossref or both) that are not accessible online (17.57% in WOS and 16.74% in Scopus). Note also the contradictory cases between Crossref and Unpaywall, where metadata from one shows OA and the other Closed, which requires further probes (22.98% in WOS and 22.91% in Scopus, these percentages are quite close to contradictions observed in the overall sample presented in Tables 3 and 4). Our effort to complement these databases proves that none of them could be used in isolation. We aim to follow-up and use PDF URLs provided by Unpaywall in large scale to control the ratio of publications which can be accessed.

Table 5: Random sample OA status check on publications from WOS

PDF Manually accessible?	Licence status	Pub OA?	Frequency	Percent
PDF Accessible	Open Access	Unpaywall OA	104	46.85
No Access to PDF	Closed Access	Unpaywall non-OA	45	20.27
No Access to PDF	Open Access	Unpaywall non-OA	18	8.11
No Access to PDF	Closed Access	Unpaywall OA	16	7.21
PDF Accessible	Closed Access	Unpaywall OA	16	7.21
PDF Accessible	Closed Access	Unpaywall non-OA	14	6.31
No Access to PDF	Open Access	Unpaywall OA	5	2.25
NA	Closed Access	Unpaywall non-OA	1	0.45
PDF Accessible	NA	Unpaywall non-OA	1	0.45
PDF Accessible	Open Access	Unpaywall non-OA	1	0.45
PDF Accessible	NA	Unpaywall OA	1	0.45

Table 6: Random sample OA status check on publications from Scopus

PDF Manually accessible?	Licence status	Pub OA?	Frequency	Percent
PDF Accessible	Open Access	Unpaywall OA	104	45.81
No Access to PDF	Closed Access	Unpaywall non-OA	48	21.15
PDF Accessible	Closed Access	Unpaywall OA	17	7.49
No Access to PDF	Open Access	Unpaywall non-OA	17	7.49
No Access to PDF	Closed Access	Unpaywall OA	16	7.05
PDF Accessible	Closed Access	Unpaywall non-OA	14	6.17
No Access to PDF	Open Access	Unpaywall OA	4	1.76
PDF Accessible	NA	Unpaywall OA	2	0.88
No Access to PDF	Closed Access	Missing on Unpaywall	1	0.44
PDF Accessible	Open Access	Missing on Unpaywall	1	0.44
NA	Closed Access	Unpaywall non-OA	1	0.44
PDF Accessible	NA	Unpaywall non-OA	1	0.44
PDF Accessible	Open Access	Unpaywall non-OA	1	0.44

Conclusions

It is clear that publishing as OA is on the rise in recent years. This trend is observed similarly in WOS and Scopus (while Scopus has higher raw publication counts but trends are identical) and based on OA identification stemming from both Unpaywall and Crossref. But still the majority of publications are closed access. We observed that despite the high coverage of Unpaywall (close to 70% of *articles* and *reviews* in both WOS and Scopus), it doesn't provide enough metadata (as of April 2018) for OA categorization thus could be limiting for large scale OA monitoring in the leading bibliometric databases. Licence information from Crossref is more detailed and it gives a good possibility to complement Unpaywall metadata. Although we overcame the downsides by complementing these databases, we still found further contradictions between them with manual random checks. Some publications were OA (based on their licences or Unpaywall status) while their PDF files were *not accessible* through publishers' websites. Some publications were closed access, while their PDF files were *accessible*. We found that the issue of multiple records for some publications or multiple licence information is something that needs to be seriously considered in OA monitoring. While we tried to test different scenarios in OA identification, still there are publications that won't fit into any of the scenarios and we had to categorize them as *NA* (since we wanted to keep the *Closed Access* definition as strict as possible), these are the publications that need to be further studied and usually the metadata of the OA databases are lacking for them. We propose OA monitoring activities to try to benefit from our approach in complementing the metadata from OA databases, i.e. Unpaywall and Crossref, while noting that there are contradictions between these sources. Our effort to complement these databases proves that none of them could be used in isolation.

Abstract

This research-in-progress investigates currently available means to collect data relevant for altmetrics research from search engines. Content analysis is used to study accuracy and relevance of the collected data and to assess the applicability of Google Search results for altmetrics research. The results show that although search engines contain a vast amount of data that could be useful for altmetrics research at a small scale, the data does not come without problems. A high number of false positives in the retrieved data showed that the data cannot be used as such and further research is required into improving the data collection strategy.

Introduction

Altmetrics research has investigated alternative online data sources for traces of scholarly communication and the use of scholarly outputs (e.g., documents, presentations, data and videos), with the intention of studying what these events could indicate about the attention research has received or what kind of impact research has had within, and outside of, these contexts. While altmetrics has become a popular research area within the domain of information science, the idea of altmetrics is not a new one. Webometrics, which preceded altmetrics, primarily used hyperlinks to mine information from the web in order to understand social and structural connections between websites and the organizations and people they represent. The original idea behind webometrics was that hyperlinks could provide valuable information about the connections between webpages or the websites they connect to, in a similar way that citations can provide information about the use of earlier work, which is cited by later work. The success of Google has demonstrated the value of hyperlinks and what they indicate, as counting hyperlinks has been at the core of Google's ranking algorithm (Brin & Page, 1998) from the beginning of the search engine's launch. The operators some search engines used to offer made it possible to, for instance, retrieve all hyperlinks that targeted a specific website or that originated from a specific website, or a combination of the two.

For altmetrics this would mean that it would have been possible to find all the webpages that contained a hyperlink to a specific scientific document or to all documents from a specific journal, thus providing insights into the use and popularity of specific scientific outputs. To the best of the knowledge of the authors, none of the major search engines offer currently any means to track links to a website. There are, however, commercial services that provide link data (e.g. https://moz.com/link-explorer that allows 10 free queries per month), mainly intended for Search Engine Optimization and benchmarking of competitors' web presence.

This research focuses on currently available free options for link data collection. This research will set out to investigate if, and how, hyperlinks relevant for altmetrics research could be identified and collected using the current means available. This research will test various methods to retrieve link data about scholarly outputs using Google to find DOIs (Digital Object Identifiers) assigned to a specific sample of scientific articles. In order to verify the relevance and accuracy of the methods, a content analysis will be conducted to find out what kind of results Google returns and in what context the DOI has been mentioned. The authors will also present the unsuccessful approaches that were tested and conclude with recommendations on how Google Search results could be used an altmetrics data source.

Literature review

Citations acknowledge the use of earlier work and thus they are generally thought to be recognition of valuable work. In a similar way the original idea of Google was that hyperlinks were created to link to some valuable work; whoever creates the hyperlink has judged the target webpage to have some value. The similarities between citations and hyperlinks led researchers to investigate hyperlinks under the term webometrics. It can be said that webometrics research started with the seminal paper on Web Impact Factors (WIF) by Ingwersen (1998). Much like Journal Impact Factors, the original idea with WIFs was that the number of hyperlinks per webpages in a website would give a comparable factor of the quality or impact of the organization behind the website. While different modifications of the original WIF were introduced (e.g. Thelwall, 2001; 2003), impact factors based on hyperlinks were found to be mostly unreliable due to (in contradiction to citations) non-standardized practices of creating links and the multitude of possible motivations for creating them. A great deal of early webometrics research focused on academic linking. This line of investigations showed that linking between universities was strongly connected to productivity (Tang & Thelwall, 2004) and that while higher ranked scholars attracted more links from their peers (Thelwall & Harries, 2003), this too was mainly due to higher productivity rather than quality. Data collection for webometrics research was typically conducted using one of two methods; for small scale research projects a web crawler could be set to crawl all the pages and collect link data, but for larger projects link data retrieved from open search engine APIs were used. Unfortunately, all the major search engines gradually ceased providing the retrieval of link data, which led webometrics researchers to investigate a range of alternative data sources. Vaughan and Shaw (2003) investigated the possibilities to search for title mentions, or so-called web citations, to scientific articles. This approach was further developed by Sud and Thelwall (2014) so that the resulting webpage was queried for links to the mentioned scientific paper, not just the mention of a title. A link to the correct webpage would then be further evidence of a relevant mention or citation. Kousha and Thelwall (2006) introduced URL citations, in which mentions of URLs are searched for in the text of a webpage, which could be present in either text or hyperlink form. The three approaches above, web citations, linked title mentions, and URL citations all overlap, as links can be identified with each approach but are not a requirement. These approaches have disadvantages including that they may generate false matches if the titles do not uniquely identify the article and that the volume of matches may report as low if the webpages don't mention the URL to the article when discussing it. This project will continue this line of investigations and study whether hyperlink data could be retrieved efficiently using the currently available data collection methods and whether the collected link data could be used to enhance altmetrics research.

Data and methods

A thorough studying of the current search operators suggested that Google's *allinanchor:* operator may return relevant results for altmetrics purposes. According to its documentation (goo.gl/MqS1jJ) the operator should return webpages that contain all the queried terms in a backlink or an anchor linking to another webpage. For instance, a query using -- allinanchor:"cats and dogs" -- would return all pages that have all the queried terms in an anchor on the page. Our hypothesis was that this approach could work as a work-around for the *link:* operator, which no longer exists. The authors utilized the Top 10 papers from the 2017 Altmetric.com listing as a starting point to test available methods for data collection.

The *allinanchor:* operator was tested using both titles of scientific articles and their DOIs. When using the operator to search for titles, many of the webpages listed in the search results contained the queried terms or the title phrase in the title of the page or in text form somewhere in the content, instead of finding them in anchor text in the content of the page.

The operator worked even worse when using DOIs as search terms, returning some false results for the tested queries. This may be due to the special characters commonly found in DOIs. These findings suggest that in certain cases the use of the *allinanchor:* command includes results that do not meet the parameters of the command. Based on these initial results, the authors argue that there seems to be minimal added value when using the *allinanchor*: operator over the approach using title mentions (Vaughan & Shaw, 2003).

Next, the authors examined searching for so-called URL citations, or for the URLs in text format (Kousha & Thelwall, 2006). This was found to not be a viable option as the results contained partial matches in many cases; for instance, a search for: **https://doi.org/10.1016/s0140-6736(17)**32252-3 would return webpages containing results such as **https://doi.org/10.1016/S0140-6736(17)**31352-1 and **https://doi.org/10.1016/S0140-6736(17)**33001-5, which matched only the first part of the query (in bold). Leaving out the domain and using only the unique DOIs returned similar results in subsequent tests. A search for: 10.1016/j.respol.2017.02.008 returned both webpages that contained the queried DOI and webpages (or other online content) with only partial matches. This approach does, however, work better for queries that do not include any special characters, such as '(' or ')'. For instance, a query for: 10.1038/nature23305 appears to return pages matching the query.

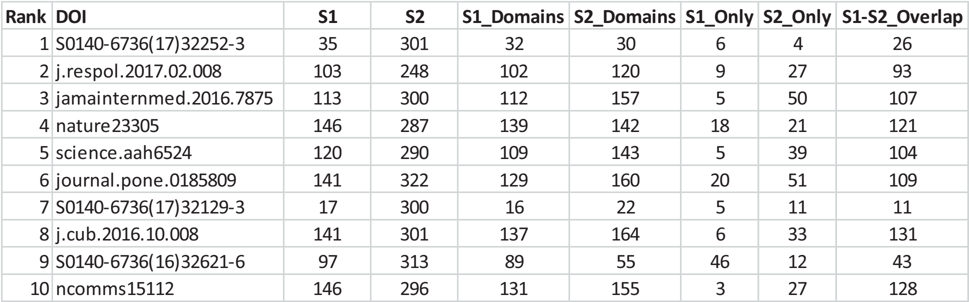
The third method tested was to search for partial DOIs (leaving out the journal identifier component of the DOI). In other words, for the DOI mentioned above the first part would be left out and the search would be done for *nature23305* only. While this strategy seemed to return a higher number of results, the approach was not without issues. First of all, the estimated numbers of hits that Google provides for all the queries made were found to change even between consecutive repeated queries. Google presents an estimate of the number of hits for any given query and it is well known and admitted by Google that this number is not accurate (https://support.google.com/gsa/answer/2672285?hl=en). For instance, Google might state that a particular query has 50,000 results, but as one goes through the results page by page the estimate reported by Google may change. These changing estimates may result from the accuracy of the estimate increasing as Google retrieves more and more results. Furthermore, after navigating through a number of result pages Google states that "in order to show you the most relevant results, we have omitted some entries very similar to the [number] already displayed" and the number of estimated results decreases significantly. Choosing to include the omitted results again changes the number of estimated results and the number of presented results. Moreover, the listing of results stops after navigating through a variable number of pages. Based on these tests, it appears that Google does not provide more than approximately 300 hits, at least for the type of queries tested here. It is possible that the algorithm determines that the relevance of the results is significantly lower after the first 300 results, thus providing more results would not be cost-effective. These variations in result estimates, omitted results, and the ceasing of displaying results after a number of pages have been viewed suggests that Google estimates should not be used as an indicator of any type.

After testing the various data collection strategies, the authors used the partial, article identifying DOIs and performed a Google search, separately collecting the results that both included and excluded the results that Google had first omitted. The two datasets were compared and the first set of results was ultimately used as a data set for content analysis. This decision assumed that most Google users would utilize this set of results, ignoring the results that Google omits from their searches. A content analysis approach was used to determine whether the results contained any false positives, i.e. results that did not contain a reference to the searched DOI. The authors also determined what type of webpage or website the DOI was found within and in what context the DOI was mentioned. The classification scheme developed for this study utilized a grounded theory approach (Glaser and Strauss, 1967) to determine the type of page and context in which the DOI was discovered. The initial classification of the type of page resulted in 119 categories. Categories that were judged to overlap significantly were merged, resulting in a total of 18-page categories. Cohen's κ was run to determine if there was agreement between two authors on the type of pages returned in the search results for 10 percent (n=31) of the coded results. There was good agreement between the two authors' categorizations, κ = .646 (95% CI, .300 to .886), p < .0005. The classification of the context resulted in an initial set of 14 categories; after merging similar and/or overlapping categories the final number of context categories was 4. Cohen's κ was run to determine if there was agreement between two authors on the context of the DOI found in the page for 10 percent (n=31) of the coded results. There was moderate agreement between the two authors' categorizations, κ = .595 (95% CI, .300 to .886), p < .0005.

Results

The results from the data collection identified several issues that require further analysis (Table 1). It would appear that if the search term includes special characters such as parenthesis, the results may be lower. It would also appear that when including the results first omitted by Google the results are constantly capped at approximately 300 results. It is also clear that the results first omitted by Google do not only contain similar pages from the same domain; in all but two of the cases the results including the omitted results included more unique domains.

Table 1. Results from the data collection (S1 = Search results, excluding the results omitted by Google, S2 = Search results, including the results omitted by Google, S1_Domains = Unique domains in S1, S2_Domains = Unique domains in S2, S1_Only = Domains only present in S1, S2_Only = Domains only present in S2, S1-S2_Overlap = Domains found in both S1 and S2)



Rank	DOI	S1	S2	S1_Domains	S2_Domains	S1_Only	S2_Only	S1-S2_Overlap

10	ncomms15112	146	296	131	155	3	27	128

A random sample of 300 results from the first set of search results (S1) was taken for content analysis. The content analysis included analysis of 1) the types of pages that contained a mention of the selected scientific papers, and 2) the context in which the paper was mentioned or the intention of mentioning it.

Type of page. As seen in Table 2, most of the resulting pages were scientific articles or pages of scientific journals (16.0%), followed by pages of university repositories for scientific papers or other databases or types of listings of publications (15.0%), and finally mainstream news sites (12.3%). As evidence of the dynamic nature of the web, 8% of the resulting pages could no longer be accessed, as they have most likely been taken down sometime between Google's last crawl of the page and the date when the data was analyzed. Companies and organizations of different kinds, research centers and scientific societies, and blogs constituted for approximately 6% of the mentions each. Websites advocating different causes and social media postings captured by Google constituted approximately 5% of the mentions.

Table 2. Type of page

Type of page	**n**	**%**
Scientific text or journal	48	16.0
Repositories, databases and listings of scientific texts	45	15.0
News site	37	12.3
Page not found or access denied	24	8.0
Companies, hospitals, governmental agencies	19	6.3
Blogs (personal, company, news, course, etc)	18	6.0
Research centres and scientific societies	18	6.0
Advocacy and initiative site	16	5.3
Social media postings	16	5.3
Press releases and newsletters	12	4.0
Online CVs and professional profiles	9	3.0
Powerpoint	9	3.0
Online magazines	7	2.3
File sharing	6	2.0
Google Books	6	2.0
Online video	4	1.3
Course sites	3	1.0
Reports and meeting protocols	3	1.0
Total	**300**	**100.0**

Intention of linking. In the majority of the investigated websites and webpages the intention of mentioning or linking to the scientific articles (Table 3) was to reference them (67.7 %, n = 203). These references were, for instance, in other scientific articles, news stories, blog entries, other social media, press releases, and magazines. In the category labelled Listing, the investigated article was found in various listings of a number of scientific articles (6.7 %, n = 20). In about 8% (n=25) of the cases the DOI was found on a webpage about the investigated article, such as the publisher's page for that specific article. In 17.3% (n=54) of the cases no mention of the investigated article could be found on the page. This category includes the 24 cases where the page was no longer available, but also includes 30 cases where the page was visited and no mention or reference could be found. It is possible that the page had been updated and the reference had been removed, but it may also be possible that the page had been indexed and resulted in a false positive to the set query, as was discovered to be the case in 10 of the results. Two of the DOIs in the sample were found to result in false positives in the search results: j.respol.2017.02.008 and j.cub.2016.10.008. A careful examination of the search results revealed that partial hits of the search terms could be found among the results. In these cases all the parts of the DOI could be found on the page, but not in a single string, for instance, "j.respol" could be found somewhere on the page, while "2017.02.008" could be found in connection with another journal identifier somewhere else on the page.

Table 3. Intention of the mention/link

Row Labels	**n**	**Percent**
Reference	203	67.7
Not found	52	17.3
Investigated paper	25	8.3
Listing	20	6.7
Grand Total	**300**	**100.0**

Discussion

This research set out to investigate Google Search results as a potential data source of altmetrics. The investigation included identifying and testing potential data collection methods and an assessment of the accuracy of the results of these tests. The results indicate that Google Search can be used to discover websites and webpages that mention specific scientific articles, but due to the lack of open APIs the approach can only be recommended for small scale projects where the obtained results can be manually investigated. In addition, the results suggest that collecting altmetrics data using Google Search is not without problems.

Google omits some search results, possibly judging them to contain duplicate content to a page already shown in the results or to be of low quality or irrelevant to the search, resulting in algorithmic penalty. Based on the findings from this study, the omitted results contained domains that were not already among the results listed, thus ruling out the cause being duplicate content in some instances. In addition, for an unknown reason Google appears to cut off the results at approximately 300 listed results. Further research is required to understand the reasons and impact these algorithmic decisions have on the applicability of Google Search for altmetrics. Furthermore, the number of false positives in the data is a concern and some automated approach should be developed to minimize the number of these occurrences.

Future research should take the limitations of this research into account, specifically that this research only analyzed the DOI search results from the top 10 papers from the 2017 Altmetric Top 100 list; different results may be obtained from an expanded data set. However, the high number of false positives for the relatively small dataset used in this research can already be seen as critical evidence against the usefulness of search results for altmetrics. Google was the only search engine used and other search engines may provide different results. While the results of this investigation showed that search data can contain relevant data for altmetrics research, future research should further determine the applicability of search results for altmetrics research by investigating possible automated approaches for large scale data collection, filtering, and analysis, possibly using the data collected by Common Crawl (http://commoncrawl.org/). Future work could also include a content analysis of the omitted search results, which may reveal new information about Google's ranking algorithm. As many users most likely use the results that Google provides, the ranking algorithm has great power in dictating what people find and what is omitted from them. It would be highly important to better understand how Google decides what to, and what not to, display as results.

Abstract

How does government activity connect to innovation? This question remains unanswered in the literature, leaving a huge gap for policymakers and academics. In the US, a government-interest statement in a patent indicates that the US federal government holds a financial interest or a right over the innovation being patented. This offers a window to examine the possible relationships between federal funding and technological advancement. Hence, this paper addresses the following research questions: 1) How does federal agency support for utility inventions accelerate innovation? 2) Which sectors are most helpful in communicating the relationships between funding and invention? 3) Is there variation in the technological fields federal agencies fund? This analysis of US patents granted between 1980 and 2017 seeks to shed light on the pattern of federal agency support for innovation. The results should be instructive and useful for strategic planning by managers and decision-makers.

Introduction

In an era of economic globalization where knowledge is the main currency, innovation has been an inexhaustible driving force of national sustainable development and progress. It is, therefore, no wonder that policymakers and academics have shown great interest in ways to improve the innovation capacity of a nation. Among all the innovation paradigms, technological innovation has become a leading factor in the competition among nations, regions, and enterprises. Technology is becoming increasingly important in the pursuit of competitive advantage that determines the final outcome.

Patenting rates and patent propensity have long been used as a well-grounded proxy for measuring technological innovations in the literature (Burhan et. al, 2017). For example, Furman et al. (2002) used patent data to evaluate sources of difference among countries in the production of visible innovative output. Mathews et al. (2005) defined patents as the ability of a country to produce and commercialize a flow of new-to-the-world technologies. There's been a growing consensus that government plays an irreplaceable role in the rate and direction of inventive activity. And the most productive and diverse technological trajectories are likely to build on government-funded inventions (Corredoira et. al, 2018). However, revealing and accurately quantifying how the process of public investment promotes and accelerates innovation remains a difficult undertaking. Proper reporting about the metrics of this paradigm assist the government in determining whether it should exercise its retained rights.

In 1980, government-funded innovation reached a turning point with the US Senate passing the University and Small Business Patent Procedures Act, now known as the Bayh-Dole Act. The key change made by Bayh-Dole was in the ownership of inventions subsidized by federal funding. Before the Bayh-Dole Act, federally-funded research contracts and grants obligated inventors, wherever they worked, to assign the rights for those sponsored inventions over to the federal government (Stevens, 2004). Whereas, with Bayh-Dole, a university, small business, or non-profit institution has the option to pursue ownership of the invention (Loise & Stevens, 2010). If the inventor does claim title, the government still retains a royalty-free license to use the patented technology. Bayh-Dole imposes several requirements, one of which creates a record labelled "Government Interest". The label means that any indication of interest or rights the US government may have on a particular patent is contained in the text of the patent document. This "government interest" statement alerts third parties, who may be negatively affected by improper use of a patent, of their ability to petition the funding agency to exercise these retained rights. Although the number of patents that indicate government interest is small, these patents reveal specific areas of scientific and technological development where the United States government has invested millions of dollars.

Most previous works have focused on tracing the topics highlighted in government-funded research (Huang et. al, 2016) or exploring its socio-economic impacts and public value (Bozeman & Youtie, 2017). Few recent studies have paid attention to assessing the technological importance of patents supported by basic research funding. Rather, they are limited to investments from the private sector (Comins, 2015). This leaves a huge gap in the literature on how government investment activity connects to innovation, particularly from the perspective of bibliometrics. This gap could be filled with evidence that reveals which federal agencies are important to research funding, the dynamics of public-private partnerships, and explains the innovation paradigm. In this paper, we mainly address the following research questions: 1) What are the roles of the federal agencies in supporting utility inventions to accelerate innovation? 2) Which sectors of patent assignees helps to communicate the relationships between funding and invention? 3) Are there variations by agency in terms of technology fields?

Framework and Data

To examine the possible relationship between federal funding and government-funded patents, we first need to collect the patents funded by the federal government. As patent filing is sometimes driven by motives other than seeking protection or the actual granting of a patent, incorporating all patents, including applications, into the corpus may result in a less perfect representation of innovation. So, we used granted patents instead of patents filed in the United States Patent and Trademark Office (USPTO) as a more appropriate data source.

These USPTO granted patent data were collected from Thomson Innovation (https://www.thomsoninnovation.com), which brings together the world's most comprehensive international patent coverage and powerful Intellectual Property analysis tools. Analyses to address the primary research questions included counting the number of inventions, as represented by DWPI patent families in the data. This approach ensured that a single invention was not counted multiple times when included in different patent applications in different jurisdictions. Information about interests by federal government agencies was extracted from the field labeled "Government Interest". The utility patent is a patent that covers the creation of a new or improved product, process, or machine. They are generally treated as the very valuable assets because they give inventors exclusive commercial rights to producing and utilizing the latest technology. Therefore, in this paper, we pay attention to utility patents and exclude the other type of patents, such as Design, Plant, SIR's, Reissue, and Defensive Publication patents. Ultimately, 103,411 utility patents granted by USPTO during 1980-2017 were collected (Retrieved on October 12, 2018). We selected 1980 as the starting point because this was the year the Bayh-Dole Act was adopted. The main government-interest statements patterns are summarized in Table 1.

Table 1. The main government-interest statements patterns in the USPTO patent dataset

Sample	*Description*	*Source*
US4181139	The invention described herein may be manufactured and used by or for the Government for governmental purposes without the payment of any royalty thereon.	The invention was supported by a government department.
US4182158	The invention described herein was made by an employee of the U.S. Government and may be manufactured and used by or for the Government for governmental purposes without the payment of any royalties thereon or therefor.	The invention was produced by a government employee.
US5337603	This invention was made with government support under Contract No. W-7405-ENG-36 awarded by the U.S. Department of Energy. The government has certain rights in the invention.	The invention is licensed under a specific contract.
US6452177	The U.S. Government has certain rights in this invention pursuant to NAS7-1407 awarded by NASA.	The invention was funded by a specific funding program or project.

Taking 1980 as the base year, the growth index of granted utility patents with government-interest statements over time is shown in Figure 1. The trend illustrates that the number of utility patents issued both overall and with government funding generally increased up to 1997. A period of inflation during 1998-2009 temporarily flattened growth, followed by a marked increase in the years after. In fact, government-subsidized patents increase eight-fold from 1980 to 2017 – proportionally higher than the overall five-times growth. However, on the whole, the general growth index was similar for both.

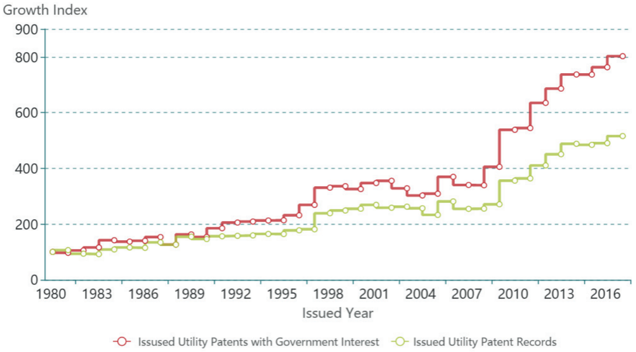

Figure 1. Growth index of issued utility patents overall and with government-interest statements

To explore these statistics in further detail, we charted the two growth rates in terms of percentages over time, as shown in Figure 2. Overall, the percentage of patents with government-interest statements has marginally grown over the past three decades but has tended to hover between 0.8% and 1.4%. As the figure illustrates, the less than 2.0% incidence rate of government-interest statements provides prima facie evidence of under-disclosure. However, this share has shifted substantially over time, rising from 1.2% to 2.0% before 2008 with a steady increase since 2009 to 2.08% in 2016 and 2017.

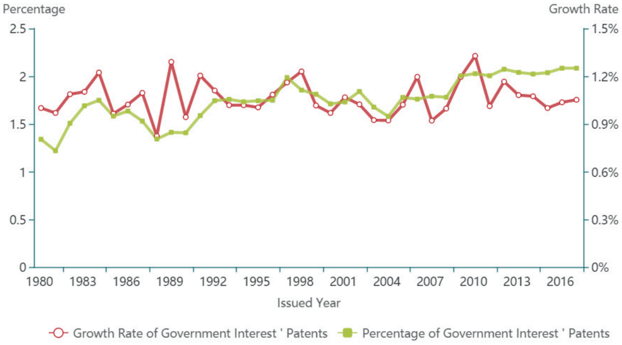

Figure 2. The percentage and growth rate of utility patents with government-interest statements

Results

This section presents the distribution of funded patents by federal agencies, patent assignee sectors by federal agency, and the technology fields funded found in the government-interest records of the dataset.

Distribution of funded patents by federal agencies

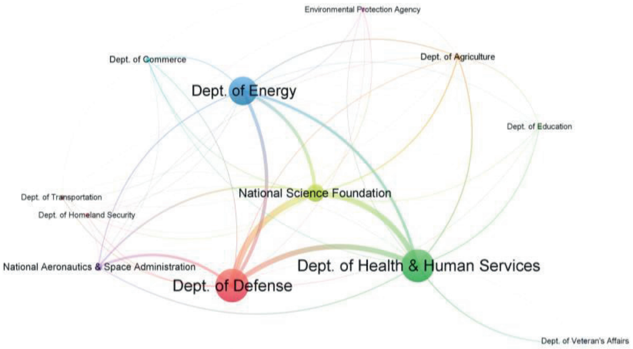
Table 2 lists the main federal agencies that supported more than 200 utility patents issued during 1980-2017. The results show the Department of Defense (DoD) is most frequently mentioned, accounting for 25.48% of the granted utility patents supported by the federal government, followed by the Department of Health and Human Services (HHS) and the Department of

Energy (DoE), who participated in 25,796 utility patent families and 20,900 utility patents, respectively. Notably, HHS is the parent agency of the National Institute of Health and the primary government agency responsible for biomedical and public health research. The National Science Foundation (NSF) also plays an important role in government-subsidized patents. The NSF is the agency that supports fundamental research and education in all non-medical fields of science and engineering.

Table 2. Top federal government agencies that supported utility patents during 1980-2017

Federal Agencies	*Records*	*Ratio*	*Federal Agencies*	*Records*	*Ratio*
Dept. of Defense (DoD)	26348	25.48%	Dept. of Agriculture (USDA)	1155	1.12%
Dept. of Health and Human Services (HHS)	25796	24.95%	Dept. of Transportation (DoT)	318	0.31%
Dept. of Energy (DoE)	20900	20.21%	Environmental Protection Agency (EPA)	275	0.27%
National Science Foundation (NSF)	10036	9.70%	Dept. of Homeland Security (DHS)	210	0.20%
National Aeronautics & Space Administration (NASA)	2870	2.78%	Dept. of Education (ED)	209	0.20%
Dept. of Commerce (DoC)	1462	1.41%	Dept. of Veteran's Affairs (VA)	208	0.20%

To further analyze joint funding by multiple federal agencies, we generated a co-funding network map of 12 agencies – see Figure 3. A node indicates an agency, and the size represents the number of patent families funded by that agency. According to the map, the leading four have a relatively strong co-funding relationship with utility patents, especially among DoD, HHS, and the NSF. This could be a signal that these agencies share common interests in certain inventions despite their different agency accountabilities. It is not surprising to see that the National Aeronautics & Space Administration (NASA) has a high co-occurrence with DoD as aeronautics and aerospace research always occupies an important position in defense and military activities.



Environmental Protection Agency
Dept. of Commerce
Dept. of Agriculture
Dept. of Energy
Dept. of Education
Dept. of Transportation
National Science Foundation
Dept. of Homeland Security
National Aeronautics & Space Administration
Dept. of Health & Human Services
Dept. of Defense
Dept. of Veteran's Affairs

Figure 3. Joint-funding map for granted utility patents by the top federal government agencies

Figure 4 shows the number of patents funded by the top four federal government agencies (DoD, HHS, DoE, and NSF) during 1980-2017. During the cold war up to the 1980s, technologies related to defense and the military received more attention, so DoD and DoE account for a greater share of the funding than the other agencies. However, with the end of the rivalry between the US and the USSR, more resources were directed toward exploring the potential of science and technology for economic development, and the number of granted patents funded by the four departments gradually began to increase, especially for HHS. The number and, in turn, amount of research funding grew rapidly under the Obama administration for all four departments but, particularly for the NSF, who received a great deal of financial support as part of America's economic stimulus plan.

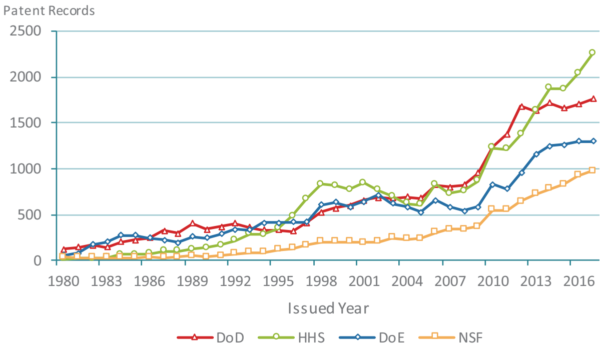


Figure 4. The annual number of issued utility patents funded by leading government agencies

Distribution of patent assignee sectors by federal agencies

Delving deeper into this analysis, we divided the patent assignees into four different sectors: academic & research, corporate, individual, and government. Figure 5 shows the annual activity in patents with government-interest statements by sector. Until the early 1990s, government assignees had the most issued patents. But, around 1994, academic & research assignees took the lead, closely followed by corporate assignees, whose role was taken over by individual assignees after 2003. The landscape shifted again in 2010 when academic & research assignees and corporate assignees jostled for the largest share leaving government-funded patents far behind.

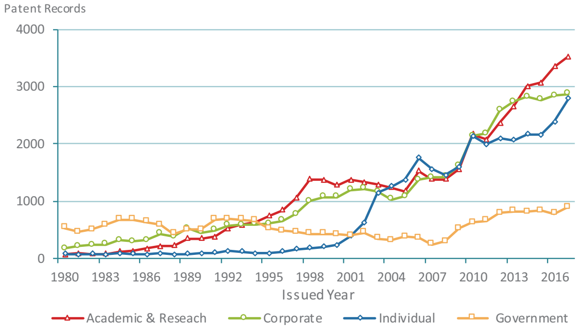

Figure 5. The assignee sectors in issued utility patents with government-interest statements

The top 10 leading assignees for federally-funded patents according to sector are listed in Table 3. Here, we see that distribution of assignees in the academic & research and corporate sectors tends to be more balanced. Whereas, in the government sector, there is a very limited group of assignees. Three subordinate military departments of the DoD – the Army, Navy, and Air Force – along with NASA and the DoE are the most notable.

Table 3. Top 10 most leading assignee in three sector assignees

NO	*Academic & Research Assignee*	*Corporate Assignee*	*Government Assignee*
1	Univ California (5821)	Sandia Corp (2554)	US Sec of Navy (5090)
2	Massachusetts Inst Technology (2653)	Int Business Machines Corp (2251)	US Sec of Army (4569)
3	Univ Leland Stanford Junior (1545)	General Electric Co (1841)	US Sec of Air Force (3198)
4	Univ Texas System (1376)	United Technologies Corp (1178)	NASA US Nat Aero & Space Admin (2612)
5	California Inst of Technology (1199)	Lawrence Livermore Nat Security LLC (2107)	US Dept Energy (2302)
6	Univ Washington (1061)	Honeywell Int Inc (1110)	US Dept Veterans Affairs (668)
7	Univ Johns Hopkins (1048)	Ut-Battelle LLC (985)	US Dept Health & Human Services (527)
8	Univ Florida (1022)	Raytheon Co (936)	US Sec of Agric (121)
9	Univ Michigan (1004)	Boeing Co (844)	US Sec of Commerce (98)
10	Univ New York State Res Found (932)	Westinghouse Electric Corp (709)	US Sec of Interior (60)

Figure 6 shows the number of patents funded by the DoD, HHS, DoE, and the NSF according to sector. The government sector has a relatively low percentage of utility patents supported by these four federal departments, but it is clear that this sector channels more of its funding into the DoE, likely due to its many national laboratories. The corporate sector receives the most support from the DoD and DoE, while universities and research institutions receive the most attention from HHS and the NSF who supports fundamental research and education across all fields of science and engineering.

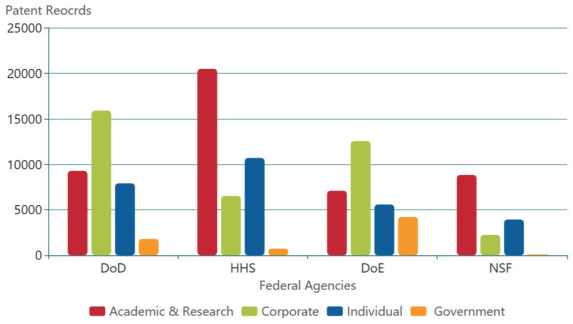

Figure 6. Patent assignee sectors supported by top 4 federal government agencies

Distribution of technology fields by federal agencies

Our third research question concerns which technology fields are most represented in government-funded research. However, appropriately classifying these fields needs careful attention. One solution is to fold the patent subclasses up into the 4-digit umbrella categories provided in the International Patent Classification (IPC) system. However, in 1992, Fraunhofer ISI and the Observatoire des Sciences etdes Technologies, in cooperation with the French patent office (INPI), developed a more systematic technology classification, called the ISI-OST-INPI classification. Their system is loosely based on IPC codes (Schmoch 2008) but has been amended several times to keep pace with the evolutions and revolutions in technological fields, so new codes are added as needed. The latest edition from the WIPO Statistics Database includes 35 technological fields that cover and balance all possible IPCs (an Excel spreadsheet is available at: www.wipo.int/ipstats/en/statistics/patents). The top 20 technology fields are shown in Table 4.

Table 4. Top 20 technology fields reflected in utility patents supported by federal agencies

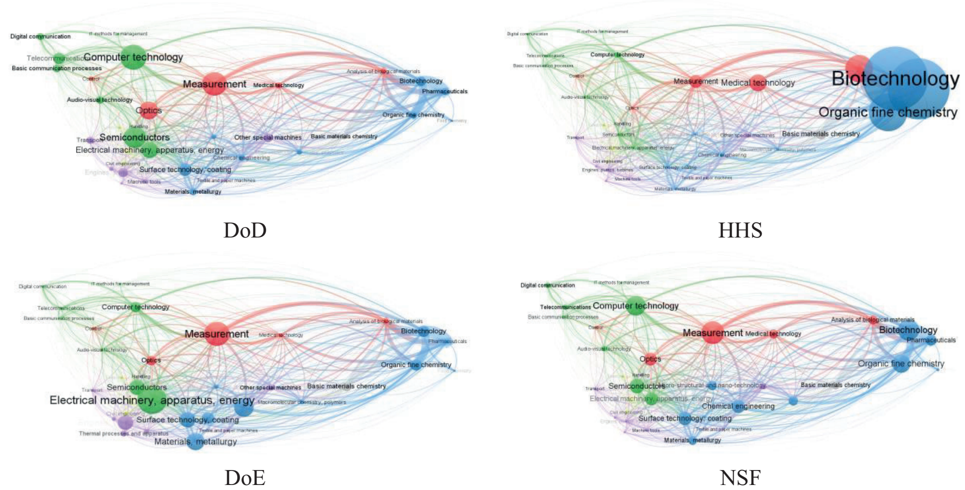
Technology Fields	*Records*	*Percentage*	*Technology Fields*	*Records*	*Percentage*
Biotechnology	20,572	19.89%	Medical technology	6806	6.58%
Pharmaceuticals	17,472	16.90%	Basic materials chemistry	6630	6.41%
Measurement	16,270	15.73%	Chemical engineering	6402	6.19%
Organic fine chemistry	13,836	13.38%	Other special machines	6169	5.97%
Computer technology	10,920	10.56%	Engines, pumps, turbines	5307	5.13%
Electrical machinery, apparatus, energy	10,039	9.71%	Materials, metallurgy	5296	5.12%
Analysis of biological materials	8917	8.62%	Telecommunications	4607	4.46%
Semiconductors	8464	8.18%	Audio-visual technology	3528	3.41%
Optics	7243	7.00%	Macromolecular chemistry, polymers	3521	3.40%
Surface technology, coating	6829	6.60%	Transport	3485	3.37%

Every patent lists at least one IPC, so the co-occurrence of IPCs can be upgraded to the co-occurrence of the 35 technology fields mentioned above. Figure 7 illustrates the structure of funded technology revealed in our analysis. The nodes represent a technology field, and the size of the node reflects co-occurring technology fields. The weight of the links indicates the frequency of co-occurrence, which are drawn in the same color if two fields belong to the same technological sector, i.e., electrical engineering is green, instruments (red), chemistry (blue), mechanical engineering (purple), and “other” (yellow).

From Figure 7, we observe that the NSF has a relatively balanced distribution of funding hot technologies compared to the DoD, DoE, and HHS. Measurement and medical technology in instruments and biotechnology are funded extensively, as is organic fine chemistry in chemistry and computer technology and semiconductors in electrical engineering. The mechanical engineering sector has received less attention from the NSF, which may be due to its inherent nature as an applied discipline.

Given the DoD is largely and directly concerned with national security, its emphasis is on technology relating to the three main types of national security: information, economic, and energy security. Our analysis revealed results consistent with these purviews: the two major sectors DoD supports are electrical engineering and instruments and, specifically, the fields of computer technology, semiconductors and electrical machinery, apparatus, and energy. Moreover, the DoD also focuses on measurement and optics in instruments, which similarly, may be attributed to the strong applicability of this sector to measuring and monitoring security. Electrical machinery, apparatus, and energy in the electrical engineering sector appear to be the focus of the DoE, which is unsurprising since these technologies are the foremost components of a nation's energy. Another obvious technology points to measurement in instruments sector. The most remarkable difference between DoE-funded technology and that of the other agencies is its relatively high attention to mechanical engineering, especially mechanical elements. We reason this is because effective protection of national energy requires sophisticated mechanical engineering technology. Materials, coatings in chemistry and metallurgy, and surface technology form further and greater support by the DoE than the other agencies, mainly due to the compatibility of these types of technologies with the features of the DoE.

Unlike the other institutions, HHS has an evident emphasis on biotechnology, pharmaceuticals, and organic fine chemistry, which fall within the chemistry sector. Biotechnology is a broad area that involves living systems and organisms as the motivation for developing products, such as pharmaceuticals. These issues are highly related to health, medicine, and human services. Therefore, it is reasonable for HHS to give priority to biotechnology and chemistry. As a highly complex subfield of chemical technology, organic fine chemistry also plays a crucial role in biotechnology development. The network map in Figure 7 makes the relationship between organic fine chemistry and biotechnology clear. Instruments is another sector that has received relatively high attention, particularly medical technology and measurement. Like biotechnology, medically-related fields are core to HHS, so it is natural for this agency to invest heavily in medical technology. However, compared to the above three institutes, HHS pays less attention to measurement, possibly because of the differences in HHS's portfolio of responsibilities compared to the other agencies.



DoD

HHS

DoE

NSF

Figure 7. The technology overlap map of utility patents supported by four federal government agencies

The above analysis reveals distinct distributions in the technology fields funded by different government agencies. As such, we replaced the 35 broad fields with 4-digit IPC categories to calculate balance and diversity at an aggregate level by patent granted year. The results dissect the annual trends in DoD, HHS, DoE, and NSF funding. Here, "Balance = 1-Geni" corresponds to a measure of evenness or balance in the various 4-digit IPC categories funded by all four government agencies across the entire period of study. The diversity measure, which comprises the components of variety, balance and disparity (Zhang et al. 2016). The results are presented in Figure 8.

Overall, the balance and diversity of the supported patents reveals significant differences over the years. This comparison shows several interesting results. First, the diversity of utility patents supported by the HHS shows much less diversity than the other three agencies, which may be due to HHS's main functions of protecting health and providing essential human services. Medical research consistently remains its clear research focus. Second, almost all of the balance indicators have tended to decrease over the past several decades with few fluctuations. Notably, these values for HHS and the NSF have been relatively stable since 1998. Third, the trend for the DoD reveals a drop in diversity over the full period, but the opposite is true for the NSF. This may tell a story of the DoD restraining its funding support to technological fields that are more directly pertinent to its institutional functions, while the NSF intends to expand its capacity to accelerate fundamental research in the non-medical fields of technology and engineering.

HHS

DoE

NSF

Figure 8. Balance and diversity indicators for issued utility patents supported by four federal government agencies

Conclusion and Discussion

The aim of this paper was to reveal the paradigm of government activity toward innovations by analyzing government-interest statements in USPTO patents. We arrived at several conclusions throughout our analyses. First, the DoD, HHS, DoE and the NSF were the most prominent federal government agencies to support issued utility patents during 1980-2017, and each has engaged in more and more utility patents in recent years. Second, in the early years of the period studied, most patent assignees fell into the academic & research and corporate sectors. However, individual assignees have shown notable performance in the past ten years. The DoD and the DoE have funded more utility patents in the corporate sector, while universities and research institutions have attracted the most attention from the HHS and the NSF. Third, the technologies that receive the most support by these four agencies, respectively, are generally in line with the agency's primary sphere of responsibilities and government functions. More precisely, the NSF has the most balanced funding structure among the four agencies, and the HHS has the most evident emphasis on medical technologies. The DoD focuses more on technologies relating to various aspects of national security, while the DoE focuses on energy and machinery.

One of the clearest paper trails between public investment offered by federal government agencies and innovation is utility patents. Federally-funded patents are not like those funded by other entities, as government funding is usually conditional on technological sectors and fields. A tentative conclusion points to the US government's interest and desire to stimulate research and development in the specific areas found in our analysis. These insights should deepen our knowledge of possible future directions in the US's national development.

However, although our research sheds some light on the pattern of federal agency support for innovation, issued utility patents are only a proxy for information that could provide a more comprehensive picture. Further study needs to be conducted from more perspectives and in more contexts. For example, do federally-funded utility patents best describe a nation's current capacity for innovation? Do these types of patents have a broad impact on later inventions? Does federal agency support closely correspond to what they care about the most across the board? Do these inventions meet the demand of the strategic development objectives they profess to Congress and the public? Each of these questions and more are worthy of further exploration.

Acknowledgments

This research is supported by the National Natural Science Foundation of China under Grant 71573085 and the Excellence Scholarship in Social Science in HeNan Province (No.2018-YXXZ-10). The HF-rating as a universal complement to the h-index

Yves Fassin[1]

[1] Yves.Fassin@Ugent.be

Ghent University, Department for Marketing, Innovation and Organisation, Tweekerkenstraat, 2, 9000 Gent, (Belgium)

Abstract

Interdisciplinary comparison has been a constant objective of the bibliometric field. The well-known h-index and its alternatives have not achieved this objective. Based on the gh-rating or *gh*ent-rating (Fassin 2018a), a categorization of academic articles into tiers of publications within similar citations ranges, a new ratio is proposed, the *high fame* hf-ratio. This ratio is calculated as the adjusted average of the weighted factors of the researchers' best articles; it leads to an associated hf-rating also designated by the symbols AAA, AA, A, BBB, B, C, D, … etc. comparable to financial ratings such as Moody's and S&P ratings.

The hf-rating provides the average grade of a researcher's best papers benchmarked in their field. This new hfrating induces some qualitative elements in the evaluation of research, includes more selectivity and mitigates between classic h-indices. Adding this hf-rating to the h-index forms a *high fame* HF-rating. This universal HFrating complements the well-known h-index with a relative indication of its influence in its field that also allows inter-field comparison. The methodology is illustrated with examples of researchers with different citations distribution from different disciplines.

Introduction

Indicators are the essence of bibliometrics (Vinkler 2010). Numerous indicators have been proposed in recent years (for a comparative overview see Yan, Wu & Li, 2016). Many bibliometricians have drawn the attention on the difficulty to grasp a complete oeuvre in a single indicator and have proposed additional elements (Costas & Bordons, 2007; Bornmann and Daniel, 2009; Zhang, 2009). Despite the conceptual weakness of any single indicator, the hindex (Hirsch, 2005) has been widely accepted as a simple indicator of a researcher's influence. But it has also been criticized for a number of drawbacks and inconsistencies (Costas & Bordons, 2007; Wendl, 2007; Waltman & Van Eck (2012). Especially its inaptitude for benchmarking researchers from different disciplines (Batista et al. 2006) emphasizes the need for contextualization (Wendl, 2007). An important disadvantage is that the h-index is not sensitive to the increase of number of citations of the most influential (highly-cited) papers (Vinkler, 2010, p. 864). Consequently, a number of variants such as the Kosmulski-index $h^{(2)}$ have been proposed (Kosmulski, 2006). More recently, a '*fame*' index f^2 has been developed, based on a categorization of academic articles, the gh-rating or *gh*ent-rating (Fassin, 2018a).

The *gh*ent-rating and refinements

Radicchi, Fortunato and Castellano (2008) pointed to the universality of citations distributions. In his recent publication, Fassin (2018a) proposed an innovative approach for a categorization of articles in function of their position in the citation distribution rank. This new rating system for academic publications, the gh-rating or *gh*ent-rating, is based on a categorization into tiers of publications within similar citations ranges. These *gh*ent-ratings are comparable to financial ratings such as Moody's and S&P ratings, with categories designated by the symbols AAA, AA, A, BA, BBB, BB, B, CCC, CC, C, D, E, etc.

The categorization makes use of a variable percentile approach based on recently developed htype indexes (Hirsch, 2005; Egghe, 2006). The levels set to categorize articles into the different categories are defined by a mix of standard levels for the higher percentile ranges (for articles with fewer citations), and the h-type percentiles for the lower percentile ranges, i.e., for articles with a large amount of citations. In practice, I opt for a model with three superposing methods to define the thresholds. The basic division rests upon the standard percentiles and two different methods at both end of the distribution ranking: h-percentiles at the top end and fixed thresholds at the lower end, expressed through a minimum number of citations (0, 1 or 2).

The principles behind those ratings lie on an exponentially increase of quality in function of the higher grades. The categories are divided in grades A, B, C, D, E and Z in declining order of citations, each with a corresponding weighted factor defined by a geometric sequence (Fassin, 2018a). The B, C and D categories are delineated through the 10%, 25% and 50% percentile. The A-category is defined through the h-percentile, the percentage of articles within the h-core of the dataset (Rousseau, 2006). The Z-category groups the articles that have not received any citation yet, and the E-category groups those articles with 1 or 2 citations, and those that have not reached the 50% percentile. Figure 1 presents the gh-rating categories on the citation distribution curve.

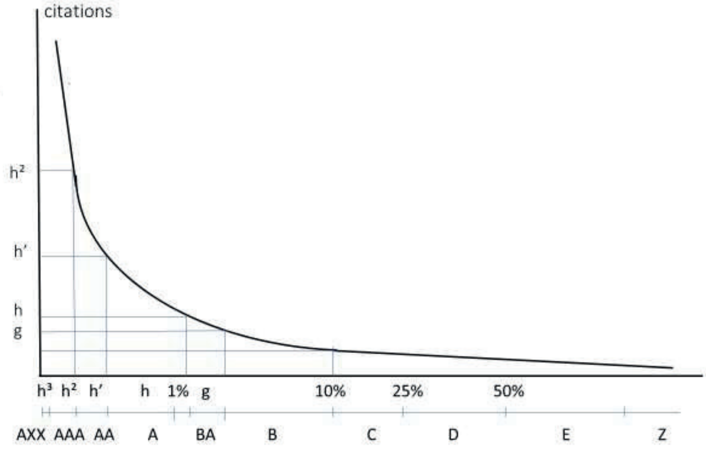

Figure 1 - The citation distribution curve and the gh-rating categories (Fassin, 2018a).

While the lower categories group a larger amount of articles (25% for D and 15% for C), the higher categories comprise around 9% (for B) or 1 % (for A). Those general categories are further subdivided into subcategories with the first letter of the general category, for example CCC, CCD, CC and C for the general category C for the 12.5, 15, 20 and 25%-percentiles.

Further subdivisions are calculated at the top of the distribution on the basis of g, h, h', h^2 and h^3-percentiles, based on their respective indexes. They define the respective AXX, AAA, AA, A and BA categories. The BA-category corresponds to the g-percentile (Fassin, 2018a) based on the g-index of this set of articles defined as the highest rank g such that these g articles together received at least g^2 citations (Egghe, 2006). The $h^{(2)}$-index or Kosmulski-index is equal to h2 if r = h2 is the highest rank such that the first h2 articles each received at least $(h_2)^2$ citations. In analogy, the h^3-index is equal to h3 articles that have at least $(h3)^3$ citations[1], for example an h^3-index of 5 means that this author has 5 articles with at least 5^3 or 125 citations (Fassin, 2018b).

The weighted factors are defined by a geometric sequence: 4, 2, 1, ½ and ¼ with the 'normal' weight of 1 assigned to the 10% percentile band (i.e. B). Sub-categories receive an intermediate weighted factor, as defined in table 1. For each of the publications that fall within the top categories, within the h-core and g-core, a bonus system is constructed: a bonus of 0.25 for the g-core, 0.50 for the h-core, 1 for the h'-core, 2 for the h^2-core, 3 for the h^3-core, is added to the starting weighted factor between 1 for the 10% B category or 2 for the higher cores of the 1% BBB category[2]. An additional bonus of 1 is added for the 0.1% highly-cited articles (for datasets over 500 units). The spread between the weighted factor reaches a factor of 50, with 6 for the most-cited papers and 0.12 for the lowest category without citations. The bonus system for the h-percentiles contributes to mitigate for different h-indexes following different databases. While the h-indexes of Scopus and the Web of Science may differ for 20%, the databases based on Google Scholars attain double of the h-indexes of the Web of Science. In this bonus system, there is still differentiation if articles within the h-core also belong to the 1% percentile category BBB or only to the 10% percentile category B.

Table 3 in appendix presents the successive rating categories with the corresponding percentile and weighted factor (see infra). The sub-categorization allows to make a better differentiation when comparing authors with less cited publications. Table 1 presents a continuum of thresholds based on percentiles and the corresponding rating categories. h-type percentiles can overlap the standard percentiles.

Normalization: the hf-ratio and the HF-rating

A constant objective of the bibliometric field has been the quest for normalization, in order to allow interdisciplinary comparison. The h-index and its alternatives have not succeeded in this endeavor. In order to compare different researcher's contribution, one could select their i best articles, and sum up their corresponding weighted factors[3].

If f_n is the contribution of the n-th paper (the weighted factor of this publication including bonus), then fi is the sum of the weighted factors of the i best cited publications: $fi = \sum f_n$. The top four fi-index f4 is thus $f4 = f_1 + f_2 + f_3 + f_4$.

[1] I will further use the symbols h^2 and h^3, rather than $h^{(2)}$ and $h^{(3)}$.

[2] Which gives 1.25 for that article if in the g-core and also within the 10% (B) or 1.50 if also within the 5% (BB). An article within the 1% (BBB) has a weight factor of 2 points; if also in the h-core it raises to 2.5; if in the h^2core it reaches 4.

[3] In difference with the f^2-index (Fassin, 2018a), that sums up the weighted factors of all the articles in the author's h^2-core.

An alternative for a more balanced comparison is to select a fixed number of the highest cited papers and to calculate the average $hfi = 1/i . \sum f_n$.

Following a common approach in statistical analysis, where often the extreme data are dropped to give a more precise measurement, I propose an adjusted average by dividing the sum of the i papers by (i-1). So, $hfi' = 1 /(i-1) . \sum f_n$ further called the researcher's hf-ratio.

This adjustment allows to avoid disadvantaging younger researchers who have no more than n papers or whose nth paper has not attained the same impact yet.

Reversed conversion of this hf-ratio on basis of same table in appendix (limited to AAA) leads to the categories for researchers, or hf-ratings, AAA, AA, A, BBB, BBC, BB, B, CCC, CCD, CC, C, D, E, etc. with corresponding percentiles.

In practice, I propose to select the researcher's most cited 4 papers (n=4). So, three A papers will give an A-rating to the researcher. A minimum hf-rating of B is obtained with 3 B papers or with 2 B papers and 2 C papers, etc. Some research fields with higher frequency of publications, often with a large number of authors, may chose a larger fixed number than 4. The division by a fixed minimum factor, 3 or (n-1), also allows to mitigate the contribution of authors with only one or two papers in the field but with exceptional amounts of citations: whereas the weighted factor f1 would give them the maximum count of 6, that only paper will give them a hf-ratio of 2. In order to distinguish occasional authors with only one or two papers from researchers with a large body of research in that field, they will receive only the basic categories *A*, *B*, *C* or *D*, put in italics.

In practice, seen the wide dissemination and acceptance of the h-index, I propose to add this hfrating, based on the converted hf-ratio, to the author's h-index to form a HF-rating (*high fame*)[4]. This new HF-rating complements the well-known h-index with a relative indication of its influence in its field that better allows comparison between peers.

The advantages of the hf-rating: Inter-field comparison

The proposed hf-rating offers some advantages, especially a possibility of comparison of the impact of a researcher within his peers. The hf-rating does not aim to rank, but leads to a rating in tiers of articles grouped in comparable categories. This hf-rating allows benchmarking. It gives the average categorization of the researcher's (i or 4) best cited papers benchmarked in his discipline or in her field.

This new hf-rating based on the *gh*ent-rating induces some qualitative elements in the evaluation of research and mitigates between classic h-indices. It includes more selectivity, and allows to single out more influential papers than the traditional h-indexes.

But the great benefit of the hf-rating lies in its universal scope of application. Thanks to its normalization character, the new HF-rating allows, to a certain degree, inter-field comparison. I will illustrate this with a practical example in a few totally different disciplines.

[4] As an alternative for a H^{3}F rating, where the hf-rating would follow the h^2-index.

Table 1 presents a continuum of thresholds based on percentiles and the corresponding rating categories. h-type percentiles can overlap the standard percentiles. The table gives the number of articles (n), the h, h², h³ and g-indexes for datasets for science in general and for each of the 4 disciplines: physics, medicine, entrepreneurship and bibliometrics, selected as 'topic' in the Web of Science search. The disciplines have been chosen on the basis of diversity in size of datasets. The four fields range from around 10.000 articles for bibliometrics over 50.000 for entrepreneurship to half a million publications for medicine or physics. The following columns in table 1 show the highest cited citation count, the required citation for the 0.1%, 1 and 10 % percentiles, as well as the required citations for the g, h, h² and h³-core.

Table 1: Distribution data of different disciplines (Retrieved from Web of Science on 21st May 2018, as 'topic')*.

Discipline	*n*	*h*	*h²*	*h³*	*g °*	*max*	*top 0.1%*	*top 1%*	*top 5%*	*top 10%*	*g*	*h*	*h²*	*h³*
Science	1555926	931	56	17	*2327*	61290	723	221	88	~40	*592*	931	3405	5509
Physics	479105	696	52	16	*1740*	21413	854	220	81	49	*401*	696	2895	4461
Medicine	485321	559	49	15	*1398*	20527	604	160	81	33	*337*	559	2027	3817
Entrepreneurship	48086	278	28	10	*695*	3527	671	199	62	29	*157*	278	822	1331
Bibliometrics	9610	111	16	7	327	795	404	120	48	27	60	111	288	403

° g-index approximately defined as 2.5*h, as total citations is not known

As an illustration of an interdisciplinary benchmarking, I present the calculation of the hf-ratio (table 2) of a selected number of researchers in those different scientific disciplines, physics, AIDS- and entrepreneurship research, and bibliometrics. For each field, I select one of the most influential researchers, and two other authors of which a younger researcher. For the entrepreneurship field, I compare the three most influential authors and a younger author. Hirsch, the founder of the h-index, is positioned in two fields: physics, where he has his largest contribution, and bibliometrics, where he only has a limited number of extremely impactful papers.

The table shows the number of publications and the total number of citations of each researcher, the number of citations of the highest-cited article (c max), the average of citations per paper, and their h and h²-indexes. Then follow the weighted factors of their 4 most cited papers, and the hf-ratio as defined supra. The table is completed with the HF-rating of those researchers.

The comparison illustrates the variety of citation habits and size of different fields that result in higher h-indexes for influential authors of broad large disciplines. In contrast, impactful authors in smaller specialized disciplines have a lower h, but comparable hf-ratios. The resulting HFrating allows – to a certain extent – inter-field comparison. The most influential authors in each discipline obtain an AAA categorization, independent from their largely different h-index: Witten with 137, Montagnier with 63, Shane with 38 and Bornmann with 36; also independent from the huge differences in total citations or number of citations of their best-cited article, about 20 times higher for Witten than for Bornmann.

The use of the hf4' variant for the hf-ratio where the 4 best papers are chosen and divided by 3 allows also to evaluate and benchmark the work of younger authors. In an absolute ranking in order of the number of papers or h-index, the researchers in physics and medicine would rank much higher than their colleagues in smaller disciplines. The comparison of the research oeuvre of Danziger-Isakov in medicine (h-index of 13 for 31 papers) with Rinia in bibliometrics (9 papers with h-index of 5) is nuanced with the A-grade for Rinia and a BB-grade for DanzigerIsakov, the average grade of their best papers benchmarked in their field.

Table 2: h-indexes and hf-ratio's of a selected number of researchers in different disciplines: physics, AIDs and entrepreneurship research, bibliometrics.

Authors	*n*	*tot cit*	*c max*	*avg*	*h*	*h^2*		*f_1*	*f_2*	*f_3*	*f_4*	*hf*		*HF-rating*	
Witten	344	93317	3088	271.3	137	29		6	4	4	4	6		137	AAA
Hirsch	264	14241	1435	53.9	57	14		6	2	1.75	1.75	3.83		57	AA
Rontynen	5	116	48	23.2	5	3		0.75	0.66	0.6		0.67		5	CC
Montagnier	246	5292	5922	99.1	63	16		6	4	2	2	4.67		63	AAA
Tan ET	77	622	166	8.1	11	5		1.5	1.25	1.25	1	1.67		11	BBB
Danziger-Isakov	31	359	42	10.0	13	5		1	1	1	0.75	1.25		13	BB
Wright	141	7692	391	54.5	50	12		2	2	1.75	1.75	2.50		50	A
Shane	61	11280	3371	184.9	38	12		6	6	3	2	5.67		38	AAA
Zahra	73	8930	664	122.3	43	15		3	3	2	2	3.33		43	AA
Minola	15	82	24	5.5	5	3		0.75	0.66	0.6		0.67		5	CC
Bornmann	249	5187	420	20.8	36	9		6	3	3	3	5		36	AAA
Hirsch	3	3695	3205	1231.7	3	3		6	4	1.75		3.92		3	AA
Rinia	9	337	124	37.4	6	5		2	1.75	1.33	1.25	2.11		6	A

Seen the exponential aspect of the categorization of the gh-rating, the categories reflect some proportionate distribution in the researcher's categorization. As a logic result, more researchers in the larger disciplines with more researchers will be able to obtain the higher ratings, than their colleagues from more limited disciplines.

Conclusion

With this extension of the application of the *gh*ent-rating, to a normalized hf-ratio and derived HF-rating, I contribute to a better method for benchmarking researchers among different research disciplines. Indeed, while the h-index and most h-type related indicators depend from the discipline, the normalization offered by the hf-ratio allows identifying tiers of comparable researchers over all fields. The hf-rating provides the average grade of a researcher's best papers benchmarked in their field.

This *high-fame* HF-rating corresponds to the call in bibliometrics for more qualitative indicators and 'responsible metrics' (Editorial Nature, 2015). The additional information provided by the HF-rating adds context to the h-index thanks to the normalization based on the universality of citation distributions.

Like many other indicators, the hf-ratio is only PAC (Probably Approximately Correct) (Rousseau, 2016). The present ratio has limitations, due to the constraints, as based on total citations, that favours established authors, and on full count for multiple authorship. Future developments should tackle these issues of researcher seniority and multiple authorship. Despite these limitations, the hf-ratio and its corresponding HF-rating offer a valuable tool for interdisciplinary benchmarking between researchers. The same methodology and HF-rating can also be applied for the benchmarking of scientific teams or universities.

Abstract

Research universities are institutions with a strong vocation and advocacy towards research. They are in the top of the world university rankings because of their excellence in research. This paper analyzes research universities focusing on their research preferences. We have selected the top twelve universities of THE World University Rankings 2019 and Scopus and SciVal as source of data with a five-year publication window. In order to analyze university preferences, we have applied a statistitical technique called cosine similarity. Besides, cluster analysis through VOSviewer showed and classified the terms most used by universities. The results have revealed that research universities have a strong commitment in specific areas. Finally, we have analyzed the scientific production in collaboration between all them and their preferences to cooperate.

Introduction

World leading universities devote to research as a central part of their mission. These institutions focus on the discovery of new scientific knowledge and future researchers training (Mohrman, Ma & Baker, 2008). Research universities make the difference with teaching universities giving more emphasis to research instead of teaching. In fact, pursuing publishing is not something that defines teaching universities. Research universities also commit to teaching as a social role of universities, but their nature is rather shaped by a research infrastructure (Taylor, 2006).

According to League of European Research Universities (LERU) the research universities are the ultimate source of innovation in the economy, society and culture. They train people to think with skepticism, creativity, and high-level capability that society demands (LERU, 2019).

The United States developed the concept of research universities. The Carnegie Classifications defines them as institutions that offer baccalaureate and doctorate programs (Carnegie Foundation, 2001). Taylor (2006) stayed that the key characteristics of leading research universities are: a) Presence of pure and applied research. b) Delivery of research-led teaching. c) Breadth of academic disciplines. d) High proportion of postgraduate research programs. e) High levels of external income. f) An international perspective.

All over the world, countries have recognized that research universities are key to the knowledge economy of the 21st century (Clark, 2004; Etzkowitz & Leydesdorff, 2000). Power & Dusdal (2017a) examined three leading countries in organizational development and scientific innovation (Germany, France and the United Kingdom). They found that global investments or the number of researchers do not influence in countries' productivity. Their findings explained that the institutionalization of research university support high productivity.

Specially, United Kingdom has a group of leading research universities that has attracted the best talent worldwide (Powell & Dusdal 2017b). Research universities are a fundamental element in the connection between research and teaching by giving freedom to teach and to study, autonomy and commitment to science as well as the hosting of future researchers.

During the twentieth century, United States (US) foster a small nucleus of productive "super research universities". This expansion was product of the increase of massive tertiary education in this nation (Fernandez & Baker, 2017). US research universities are research centers increasing the knowledge in all scientific disciplines. They are contributing to the general economy of the country and also to local and regional economies. The US university system is one of the best in the world including the number of Nobel Laureates awarded to their faculty members. Some countries have tried to imitate the model of the US university system, but with limited success. The reason is that most university systems are controlled by governments (Atkinson & Blanpied, 2008).

The Times Higher Education (THE) World University Rankings defines different criteria to include universities, three of which meet the concept of research universities: i: Enough publications – An institution must publish more than 1,000 papers over the previous 5 years, and more than 150 publications in any single year. ii. Thresholds are also applied per subject for the subject rankings. iii: Subject breadth – An institution must not be focused on a single narrow subject area.

Research questions addressed in this work are: What is peculiar about the scientific production of research universities? Is there any research preference in their publications? Do research preferences have any resemblance among them? What are the most used terms in the production of these universities? The most prolific authors, are they national or international? Are these universities collaborating with each other or are they competing among themselves? Which are the preferences to collaborate?

Data and method

We first concentrate on those research universities that state prestigious university brands. We have used the Times Higher Education (THE) Ranking World University rankings 2019 to sort the top twelve institutions. We have used Elsevier's Scopus to extract publications because it is one of the world's most comprehensive bibliometric databases and is employed by THE to calculate rankings. We also retrieved the number of publications of the top universities for each research subject in those years. These information was included in Elsevier's SciVal to apply indicators and in the VOSviewer program to create clusters and maps.

Scientific collaboration is a quality that defines leading world-class institutions since they cannot excel in isolation, as they are purpose-built for cooperation. For this reason, we have also analyzed collaboration among them.

The research universities chosen for the study are as a follows: University of Oxford, University of Cambridge, Stanford University, Massachusetts Institute of Technology, California Institute of Technology, Harvard University, Princeton University, Yale University, Imperial College London, University of Chicago, ETH Zurich, and Johns Hopkins University.

We downloaded 668,204 publications from Scopus which is all the scientific production from the universities in the period of time 2014-2018. The data for each institution was processed using the data management software program, SPSS. Data were retrieved in december 2018.

Similarity measurement among top universities

Two institutions are similar in research preference if their cosine similarity is close. This study compared the research preference using cosine similarity rather than Euclidean distance. Cosine similarity refers to cosine of the angle between two vectors. Generally, the angle between two vectors is used as a measure of divergence between the vectors. Cosine is used as the numeric similarity (where cosine has the property that it is 1.0 for identical vectors and 0.0 for orthogonal vectors) (Singhal, 2001; Zhigang, Gege, & Haiyan, 2017; Lin, Hu, & Hou, 2018)

The cosine similarity of two vectors A and B using a dot product and size as

$$\mathbf{A} \cdot \mathbf{B} = \|\mathbf{A}\| \, \|\mathbf{B}\| \cos\theta$$

Cosine similarity

$$\text{similarity} = \cos(\theta) = \frac{\mathbf{A} \cdot \mathbf{B}}{\|\mathbf{A}\|\|\mathbf{B}\|} = \frac{\sum\limits_{i=1}^{n} A_i B_i}{\sqrt{\sum\limits_{i=1}^{n} A_i^2} \sqrt{\sum\limits_{i=1}^{n} B_i^2}},$$

University performance in Times Higher Education (THE) are grouped into five areas: teaching (the learning environment) (30%); research (volume, income and reputation) (30%); citations (research influence) (30%); international outlook (staff, students and research) (7.5%); and industry income (knowledge transfer) (2.5%).

We selected the metrics: research and citations. They meet 60% of the score and they have a strong influence in the character of a research university.

- Research (volume, income, and reputation) – 30%: the most prominent indicator in this category looks at a university's reputation for research excellence among its peers, based on the responses to our annual Academic Reputation Survey. Therefore: Reputation survey: 18%, Research income: 6% and Research productivity from Scopus: 6%.
- Citations (research influence) – 30%: it examines the research influence by capturing the average number of times a university's published work is cited by scholars globally. The data include more than 25,000 academic journals indexed by Elsevier's Scopus database.

The indicators used in this study (SciVal, 2019)

- Scholarly output which is the total number of publications of an entity.
- % International collaboration indicates the extent to which an entity's publications have international co-authorship.
- Citation count is the total number of citations received by an entity. This is a complement to scholarly output.
- Publications in Top 10 Journal Percentiles, which indicates the extent to which an entity's publications are present in the most-cited journals.
- Outputs in Top Citation Percentiles, which indicates the extent to which an entity's publications are present in the most-cited percentiles.
- Field-Weighted Citation Impact (FWCI) indicates how the number of citations received by an entity's publications compares with the average number of citations received by all other similar publications.

Results

In the following table we can observe the position of the top twelve institutions in THE. We also have applied the bibliometric indicators to scientific production.

Table 1. Indicators applied to top 12 research universities

Research universities	Countries	Overall	Research (volume, income and reputation)	Citations (research influence)	Scholarly Output	Collaboration (%)	Citation Count	Publications in Top 10 Journal Percentiles (%)	Outputs in Top 10 citation percentile (%)	Field- Weighted Citation Impact (FWCI)
		Times Higher Education World University			Scopus- SCIval (2014 - 2018)					
University of Oxford	United Kingdom	96	99.5	99.1	68,034	58.7	855,705	48.7	27.0	2.3

ETH Zurich	Switzerland	89.3	91.4	93.8	38,806	65.3	445,479	53.1	28.1	2.0
Johns Hopkins University	United States	89	90.5	98.5	65,637	39.4	797,610	44.8	26.3	2.2

We can observe that the two best research universities in the world are from the United Kingdom. They are the corners of the ‘golden triangle’. Golden triangle universities have some of the largest UK university financial endowments. Followed by these are the universities of the United States where most of them are private. Currently, there are more than 250 of these institutions in the United States. In table 2 we can observe the total amount of publication and the percentage with the total of each disciplines. The average of international collaboration is 49%. Percentage of publications in the top 10 journal percentiles is 49.65 and the percentage of outputs in top 10 citation percentiles is 48%.

The colour green means acceptable values and the red colour might be a room for improvement. Most of research universities have a strong production in Medicine followed by Biochemistry, Genetics and Molecular Biology. However University of Princeton, California Institute of Technology and ETH Zurich have more production in Physics and Astronomy. We must bear in mind that scientific disciplines have different patterns of publication and some disciplines attract more economic funding than others. Both circumstances could affect to scientific production.

Table 3 shows the resulting adjacency matrix, which represents the level of similarity between two pairs of institutions.

Table 3. Adjacency matrix of top research universities' cosine similarity in research areas

	University of Oxford	University of Cambridge	Stanford University	Massachusetts Institute of Technology	California Institute of Technology	Harvard University	Princeton University	Yale University	Imperial College London	University of Chicago	ETH Zurich	Johns Hopkins University
University of Oxford	1											
University of Cambridge	0.835	1										
Stanford University	0.847	0.754	1									
Massachusetts Institute of Technology	0.799	0.826	0.747	1								
California Institute of Technology	0.870	0.772	0.790	0.806	1							
Harvard University	0.810	0.785	0.790	0.824	0.808	1						
Princeton University	0.793	0.866	0.793	0.855	0.782	0.746	1					
Yale University	0.864	0.895	0.828	0.709	0.833	0.780	0.847	1				
Imperial College London	0.784	0.797	0.772	0.713	0.844	0.755	0.812	0.840	1			
University of Chicago	0.851	0.773	0.754	0.767	0.786	0.867	0.739	0.756	0.759	1		
ETH Zurich	0.836	0.794	0.834	0.869	0.903	0.790	0.872	0.809	0.764	0.741	1	
Johns Hopkins University	0.848	0.804	0.854	0.766	0.848	0.863	0.740	0.800	0.839	0.842	0.806	1

Cosine similarity is 0.87 for University of Oxford and California Institute of Technology. This represents a strong similarity between them. However the University of Oxford and Imperial College London has a 0.784 similarity. It means University of Oxford is more like California Institute of Technology than Imperial College London in research preferences.

Next figure analyses the terms used in the scientific production of all universities together. We have chosen a map based on bibliographic data. We used fractional counting method to perform the map.

The minimum number of occurrences of a term is 100. Of 639,854 terms, 1,215 meet the threshold. For each of the 1,215 terms, we calculated a relevance score. Based on this score, the study showed the most relevant terms. The default choice is to select the 60% most relevant terms. Finally, we selected a total of 500 terms.

There are 6 clusters. Red color represents the Cluster 1- Physical sciences with 184 items. Green color represents the Cluster 2- Health sciences with 133 items. The blue color represents the Cluster 3- Social sciences with 85 items. The yellow color is Cluster 4- Life sciences with 79 items. Color pink Cluster 5 with 15 items. Finally the purple color is Cluster 6 with 2 items.

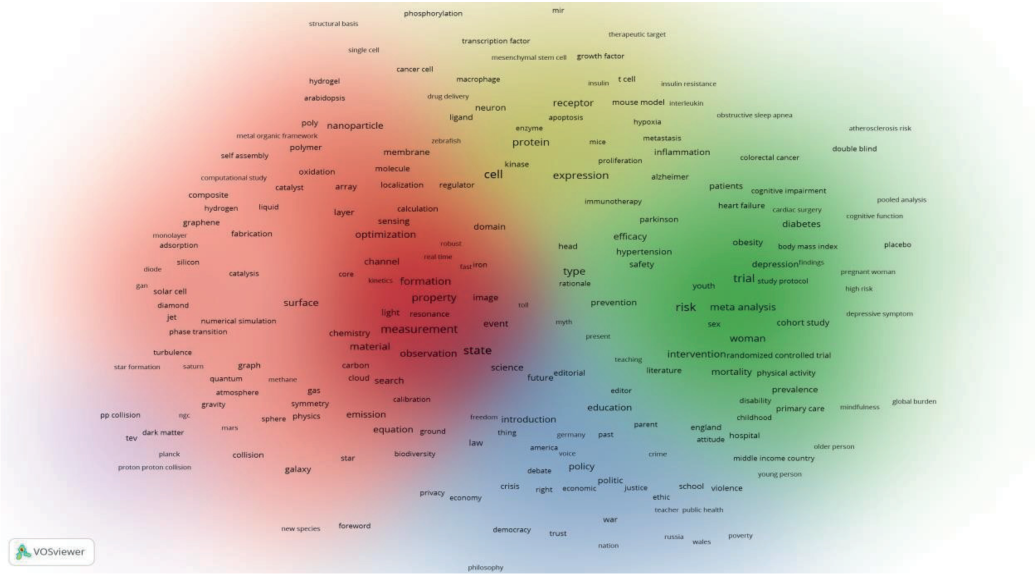

Figure 1. Co-occurrence map based on text data

Risk is the term most used in the production of universities 4,896 occurrences with a relevance of 0.81; Cell is used a number of 4,490 times with a relevance of 0.67; State is used a number of 4,197 with a relevance of 0.29; and Measurement with 3,967 occurrences and 0.82 relevance. Risk, cell, state and measurement could be the same four most common words in the publications of the universities ranked 13-200 in THE.

The next figure analyses the authors in the scientific production of all universities together. We have chosen a map based on bibliographic data for a co-authorship analysis. The fractional counting method was used for this analysis. We have ignored documents with a large number of authors only choosing 10 as the largest number of authors per document. Moreover we selected prolific authors with at least 50 documents and 200 citations. The number of citations of an author equals the total number of citations the documents of the author have received in Scopus.

Of the 450,562 authors, 1,783 meet the thresholds. For each of the 1,783 authors we calculated a total strength of the co-authorship links.

We have applied an author disambiguation process. We checked that the analyzed production belongs to each of the authors and there was no mixed production within the same name.

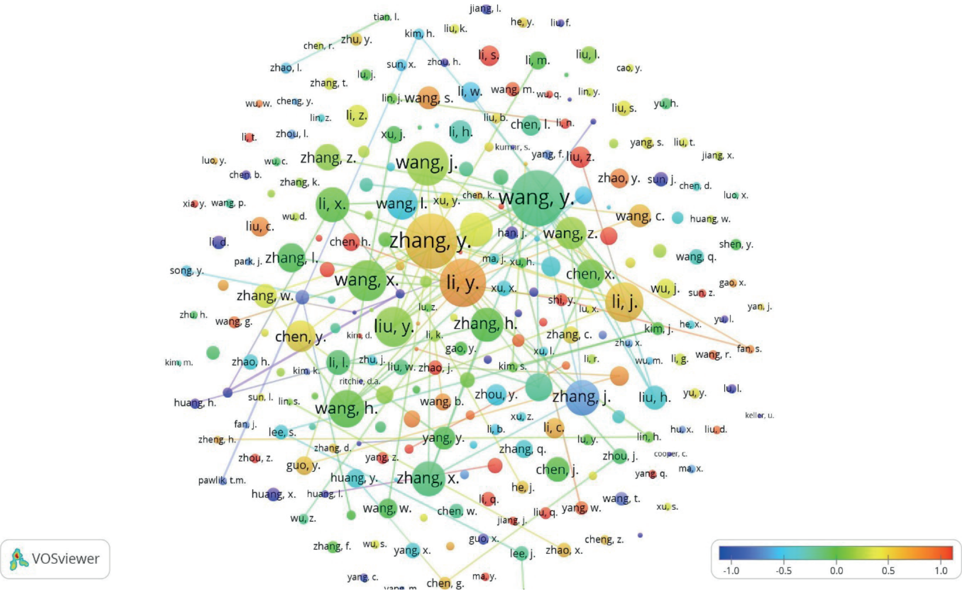

Figure 2. Co-authorship map based on bibliographic data.

There is a total of 16 clusters with 12,219 links and a total link strength of 18,099. We notice a larger amount of Asiatic names appearing the most in the documents of all these institutions.
Cluster 1 obtains the majority of items (38), followed by cluster 2 (28 items), cluster 3 (27 items), cluster 4 (27 items), cluster 5 (26 items), cluster 6 (19 items), cluster 7 (18 items), cluster 8 (17 items), cluster 9 (16 items), cluster 10 (14 items),cluster 11 (7 items), cluster 12 (3 items), cluster 13 (3 items), cluster 14 (2 items), cluster 15 (2 items), cluster 16 (2 items).
Wang, Y is the author with the largest number of documents and links. The second is Zhang, Y.

Are research universities outputs favored by collaboration with these asiatic researchers? or, are they improving the scores of these institutions as a member of staff? These research questions emerged from the results and we will study in future works.

Scientific collaboration among 12 top universities

There are 28,348 documents published in cross-institutional collaboration among those research universities. They published together 13,908 documents in Open Access (articles published in “Gold” OA, including full OA journals, hybrids, open archive and promotional OA). Alternatively, they published 14,440 in other type of access including subscription or green OA.

The next map shows the terms used in the title and abstract of the 28,348 documents in collaboration. We chose binary counting method with a minimum of 20 occurrences. Of the 63,780 terms, 472 meet the threshold. 150 terms selected to appear in the map.

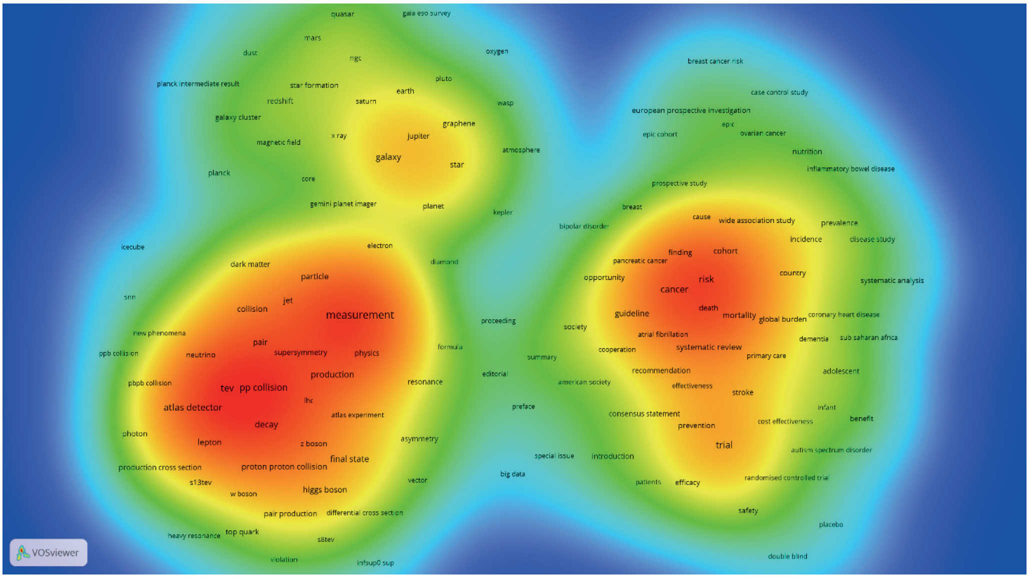

Figure 3. Co-occurrence map based on collaboration production among research universities

There are 7 clusters with 1,408 links and 11,228 link strength. Measurement is the term most repeated with 940 occurrences, a total number of 65 links. Follow by Risk with 542 occurrences and 52 links, Atlas detector with 445 and 45 links and Cancer with 433 occurrences and 45 links.

The fifteen institutions behind these collaborations: University of Oxford (8,071), University of Cambridge (7,300), Massachusetts Institute of Technology (6,963), Harvard University (6,227), Stanford University (6,003), Imperial College London (5,950), California Institute of Technology (4,624), Johns Hopkins University (3,985), University of Chicago (3,974), Princeton University (3,920), Yale University (3,911), ETH Zürich (3,273), CNRS- Centre National de la Recherche Scientifique (2,442), UCL (University College London) (2,435), University of California, Berkeley (2,174).

The funding sponsors that finance these publications: National Science Foundation (NSF) (2,437), National Institutes of Health (NIH) (2,012), U.S. Department of Energy (1,247), European Research Council (1,226), Wellcome Trust (1,097), National Aeronautics and Space Administration (1,071), Science and Technology Facilities Council (973), European Commission (870).

Table 4. Indicators applied to scientific production in collaboration among Research Universities

	Scholarly Output	Citation Count	Citations per Publication	Field-Weighted Citation Impact	Collaboration (%)	Collaboration Impact (%)	Outputs in Top 10 citation percentile (%)	Publications in Top 10 Journal Percentiles (%)
Total	28,348	760,023	27.4	3.82	69.8	30.8	45.4	61.3

Veterinary	37	299	8.1	2.53	40.5	12.2	24.3	73.5

The scientific production received a total of 760,023 citations. A Field-Weighted Citation Impact of 3.82 and a 61.3% of publications in Top 10 Journal Percentiles. The highest score in citation per publication placed in the field of Biochemistry, Genetics and Molecular Biology (30.6), Chemical Engineering (30.5) and Medicine (29.6). The top Field-Weighted Citation Impact (FWCI) is in the field of Medicine (5.17). The highest percentages of international collaboration are in Earth and Planetary Sciences (83.5), Physics and Astronomy (81.8) and Environmental Science (75.9).

Apart of Multidisciplinary, the fields with highest international collaboration impact are Medicine, Biochemistry, Genetics and Molecular Biology and Physics and Astronomy. The outputs in Top 10 citation percentile are in Chemistry, Chemical Engineering and Biochemistry, Genetics and Molecular Biology. The publications in Top 10 Journal Percentiles are in the field of Agricultural and Biological Sciences, Dentistry and Environmental Science.

Conclusions

The study analyzed research preferences of Top-12 research universities according to the last edition of THE ranking 2019. We have used the Scopus database to extract data and SciVal to apply indicators with a 5-year publication window.
The percentage of international collaboration is 49%. Percentage of publications in the top 10 journal percentiles is 49.65 and the percentage of outputs in top 10 citation percentiles is 48%. Research universities published in the area of Medicine. But others like MIT - Massachusetts Institute of Technology, California Institute of Technology, Princeton University focused their production on Physics and Astronomy.
Cosine revealed the similarity of universities with more analogous research preferences and others. For example California Institute of Technology and ETH Zurich or University of Cambridge with University of Princeton.
Cluster techniques classified outputs into Life Sciences, Physical Sciences, Social Sciences and Health Sciences. The majority of terms from research universities concentrate in the Physical Sciences cluster.
From the co-authorship map have extracted a great number of Asiatic names. This motivates us to investigate if they are responsible of raising scientific production and impact of these universities.

Research universities have 28,348 in common. They are collaborating the most in Physics and Astronomy, Medicine, and Biochemistry. University of Oxford is the most collaborator institution.

Next steps and future works

In future research, we will compare the research patterns of the lower ranked research universities with the Top-12. At the same time, we will analyze the scientific collaboration between the runners-up universities and top universities to know the benefits obtained from this diversity.

We motivate research universities to become more strategic, successful, and quality-oriented in their collaborations.

An emerging recommendation from this study is that governments and private companies such as Fortune 500 companies should do more research investment in universities since it is clear it becomes a profitable asset. The future in rankings will depend more on corporate policies for financing research. It is an imperative need to invest in universities and adopt measures to improve the quality of education and research to become a key player in the higher education sector in the world sphere.

Measurement variation in bibliometric impact indicators

Abstract

The bibliometric measurement process transfers scientific publications and citations into indicators on scientific impact. In defining specific measurement paths researchers hold several degrees of freedom as various methodical decisions are scarcely founded on stringent criteria and their respective implications are not fully understood. These diverse measurement paths result in varying measurements. We propose to compute many possible measurement paths and to analyse the resulting measurement variation. On the one hand, effects of decisions can thus be better understood and on the other hand the resulting measurement variation should be taken into account when using impact values for e.g. funding decisions.

Introduction

Bibliometric indicators result from a measurement process which converts scientific publications and the included references into aggregate values. While the particular selection of citations arises from complex und partially unobserved mechanisms and consequently could be modelled via a stochastic approach, the data generating process of the deterministic bibliometric measurement is perfectly known. The measuring researcher decides upon the process and defines a specific measuring approach, e.g. the choice between Web of Science and Scopus. Figure 1 presents three exemplary measurement decisions, which lead via different measurement paths to eight varying values on the same bibliometric impact indicator.

Figure 1: Measurement paths in an exemplified garden of forking paths for a bibliometric analysis.

In defining a particular measurement approach the researcher holds several degrees of freedom, as the implications of each single measurement decision are not fully understood and furthermore the content to be measured, e.g. scientific productivity or impact, consists of latent constructs. The exact extent to which scientific impact is comprehensively covered via citations is disputed (MacRoberts and MacRoberts, 2018), while at the same time citations to an unknown degree occur due to aspects unrelated to scientific impact (Latour & Woolgar, 1986). Citations and scientific impact overlap, but they are not congruent - as any missing Mertonian citation and any existing non-Mertonian citation decrease the signal-to-noise ratio of a citation based measure of scientific impact. Due to the lacking justification of measurement decisions and the lacking clearness about the content to be measured, no – in a statistical sense – true or optimal measurement path might be identified. Instead, several diverging measurement paths through the so-called garden of forking paths (Gelman and Loken, 2014) co-exist. However, most measuring authorities opt for a single measurement path (e.g. CWTS, 2018). In contrast, we propose to embrace this variety and compute several measurement paths. The resulting fuzziness might be understood as a measurement variation. Due to its known and deterministic origin it might not be qualified as a stochastically induced variance, but highlights uncertainness of the measured values caused by the measurement process.

A conceptual model of variation in bibliometrics

The analysis of variation in bibliometrics is predominately discussed in terms of a stochastic variance. In a recent contribution Williams and Bornmann (2016) assume randomness in bibliometric citation counts and propose frequentist statistical inference techniques to quantify its magnitude. For example Bornmann (2017) proposes the estimation of parametric confidence intervals for Journal Impact Factors. Thelwall and Fairclough (2017) extend this approach by proposing a partially randomly determined capacity to produce impactful research observed via publications. Apart from these parametric approaches also non-parametric techniques like bootstrapping (Waltman et al., 2012) and the jackknife (Saḡlam and Friggens, 2018) have been applied. However, these modelling approaches mostly do not account for the data generating process, but rely solely on the observed cross-sectional variation arising in a single measurement path. Furthermore Schneider (2016) argues that frequentist statistical inference on populations is inappropriate. Recently the debate on p-hacking and the reproducible crisis has inspired research to focus on modelling decisions (e.g. Gelman and Loken, 2014; Rohrer et al., 2018). In bibliometrics, the synchronous presentation of different measurement approaches is usually restricted to a limited subset of single parameters, like database coverage (Archambault et al., 2009, Struck et al, 2018), self-citations (Mittermaier et al., 2016) or fractional and whole counting (Waltman et al., 2012).

Physical World

Figure 2: Conceptual model of measurement variation

Figure 2 presents a model detailing how such different measurement paths are embedded in the wider mechanism of the science system. We assume several distinct layers which are inter- and intra-related. The bottom layer of the physical world is related to the space of knowledge claims understood as the (debated and extending) knowledge on the physical world. The next layer of the externalization space depicts observable artefacts i.e. documented claims as publications and explicit (e.g. citations) and implicit (e.g. author keywords) links between them.

The topmost layer of the measurable spaces is central to our analysis. The transfer of artefacts from the externalization space to diverging measurable spaces is thought to be governed by diverse measurement paths. As the externalization space is too large to be observed in its entirety, the measurement path extracts a subset of artefacts and consequently renders them accessible to the bibliometric measurement. However, different measurement paths equally co-exist and each path defines a separate although potentially overlapping measurable space. Any such measurable space might be equipped with a counting measure and consequently bibliometric statistics might be calculated. Hence any variation in the measurable spaces consequently causes variation in the values of bibliometric indicators. Given the unknown ground truth of the scientific impact each of these single incarnations of the same indicator maps the respective scientific impact of an entity to a different value constructing en passant separate realities (Desrosières, 1998), upon which funding and policy decision are made.

A quantitative description of measurement variation

For this research-in-progress paper we focus our analysis on eight binary measurement decisions, which result in 256 different measurement paths and values of the same indicator for the same analysed entity. As publications and citations have to be counted separately for every path and are to be supplemented with field-specific expectancy values, we limit our analysis to a computationally feasible random sample of 25% of all potential measurement paths, i.e. we compute 64 parallel bibliometric worlds defined by the respective randomly drawn measurement paths. The following measurement decisions were taken into account: (1) Web of Science or Scopus, (2) include or exclude Non-English publications, (3) combine or separate reviews and articles in normalization, (4) include or exclude self-citations, (5) include or exclude Social Sciences and Humanities (via OECD Fields of Sciences), (6) apply fractional or whole counting to multi-author papers, (7) three-year or five-year citation window and (8) discipline classification by database provider or OECD Disciplines of Sciences.

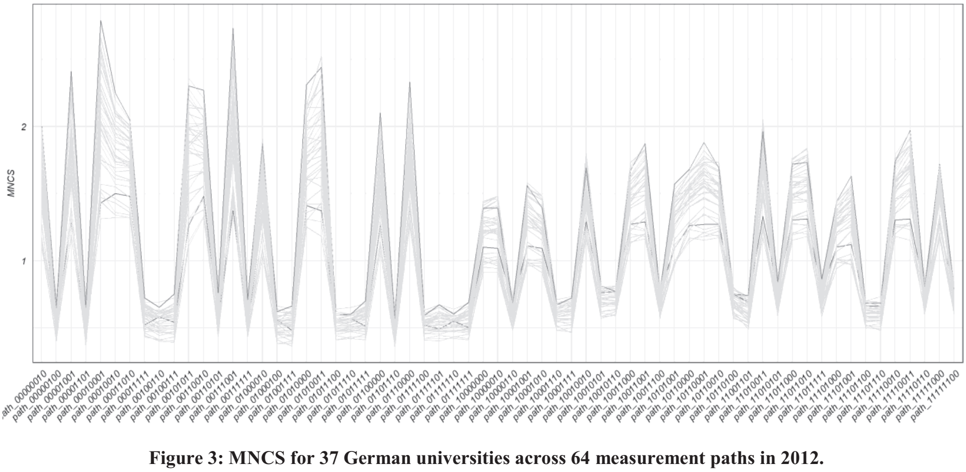

Figure 3: MNCS for 37 German universities across 64 measurement paths in 2012.

For each of these constructed bibliometric realities we compute the *Mean Normalised Citation Score (MNCS)* for every German university. Figure 3 illustrates a preliminary description of the resulting measurement variation. Every line indicates the respective MNCS values (y-axis) across the measurement paths (x-axis) for one of the 37 universities. For example, the

Universität Heidelberg observes a more pronounced variation with values between 0.6 and 2.75, while the equivalent interval for the Freie Universität Berlin starts at 0.5 and ends at 1.5. Given that the value of 1 is commonly understood as the world average, the Universität Heidelberg (Freie Universität Berlin) might find its citation impact in the interval of being 175% (50%) better or 40% (50%) worse than the world average. Consequently the information value on the actual bibliometric impact state seems dubious. Obviously this substantial variation might not be observed if the analysis is limited to a single measurement path. Apart from this institutional perspective on the variation the relative position of these two universities among all other 35 German universities does not vary to a large degree.

In order to gauge the stability across the measurement paths Figure 4 presents the rank-based Spearman correlation matrix between the 37 German universities' MNCS in each of the 64 parallel bibliometric worlds, i.e. every small square colour codes the Spearman correlation in the ranking of the same universities across two measurement paths. Dark blue symbolizes a strong accordance in the ranking of the respective measurement paths, while white denotes no accordance. Negative correlation does not arise.

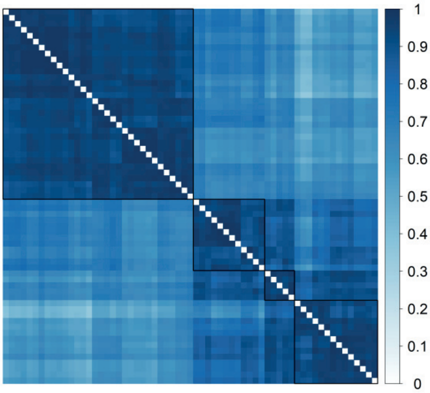

Figure 4: Spearman correlation matrix across the MNCS of 37 German universities resulting from 64 measurement paths.

The correlation matrix has been ordered according to a hierarchical Ward clustering to allow an inspection of the structure causing the aforementioned stability. Four dominant cluster can be identified, the first and biggest one in the upper left corner, the next one in the lower right corner, a third one in the middle and a comparable small one just below on the diagonal, all marked by black lines. The biggest cluster at the upper left corner is constituted by all Spearman correlations between measurement paths based on whole counting, which seem to render greater stability than fractional counting in this preliminary state. Consequently the square to the right (and bottom) of this cluster denotes the rather inconsistent Spearman correlation between whole and fractional counting. On the lower right corner, we find all measurement paths applying fractional counting for the Web of Science, while the equivalent paths for Scopus are subdivided into two clusters. Thus Web of Science seems to be a more stable and probably coherent base less affected by single measurement decisions. The cluster in the middle incorporates measurement paths based on Scopus and fractional counting and the OECD classification, while the smallest cluster holds measurement paths based on Scopus, fractional counting, the Scopus ASJC discipline classification, only English publications and including the social sciences and humanities (SSH). Hence German universities with their rather large corpus of non-English publications in the SSH seem to be uniformly affected by the enlarged database of Scopus in the SSH and Scopus's ASJC discipline classification. These structural observations will be modelled in the next section to infer the direction and size of these effects.

Modelling measurement variation

We model intrinsic values independent of the measurement process by employing a linear mixed model

$$Y_{ij} = \alpha_i + x_{ij}^t\beta + u_{ij}^i\gamma_i + \epsilon_{ij}$$

where

Y_{ij} indicates the *MNCS* of university i corresponding to measurement path j

$i \in [1, \ldots, m]$ denotes the $m = 37$ German universities

$j \in [1, \ldots, n_i]$ states the balanced size of $n_i = 64$ observations per university arising from the diverse measurement paths

α_i denotes the university specific (random) intercept

β describes the vector of fixed effects of the eight binary measurement decisions and

γ_i details the random effects of these measurement decisions on the university i.

Hence the effect of the measurement decision on the universities' MNCS is composed of an overall effect β and an individual effect γ_i allowing for a large degree of flexibility. As we analyse the same 37 German universities in the 64 different measurement paths, we assume the respective MNCS values of the same university to be related throughout all measurement paths and hence obtain a cluster of related MNCS values for every university. The university specific intercept denotes the constant, unaffected part across the observed MNCS values of all measurement paths and accordingly might be understood as the citation-based latent scientific impact irrespective of the variation caused by the measurable spaces of Figure 2.

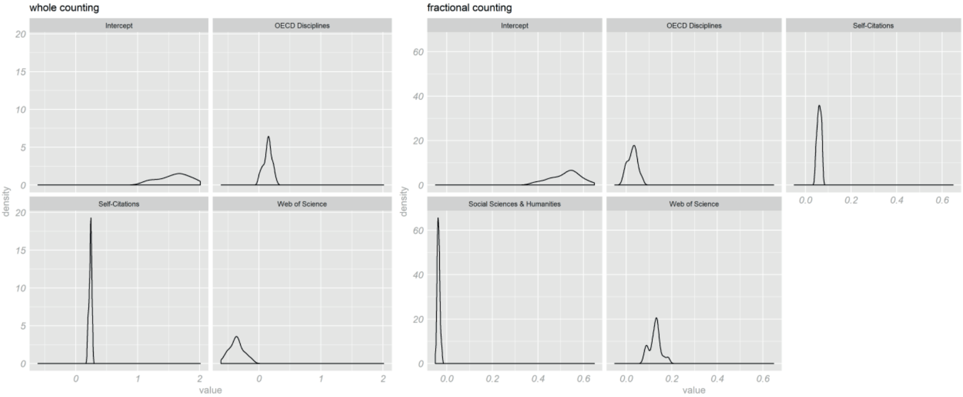

Figure 5: Distribution over German universities of the composed effect of the measurement decisions on the respective MNCS by fractional and whole counting.

The direction and size of the diverse measurement decisions are depicted in Figure 5. Due to fitting issues in this research-in-progress paper we still not present an overall model, but separate models for whole and fractional counting. However, the effect of whole and fractional counting might be inferred from a comparison of the intercepts. Fractional counting reduces the MNCS to a large degree, as observable by the different scales in the x-axis. The application of the broader OECD discipline classification improves the MNCS values slightly, but to a varying degree. Some universities gain more than others from applying the OECD disciplines, possibly due to different disciplinary profiles. The positive effect of including self-citations does not vary to a large degree across universities. However its positive effect allows to infer that

German authors cite themselves more often that the average global author. The inclusion of the SSH reduces the MNCS slightly for fractional counting, while we observe no such effect for whole counting. We also observe no overall effect of non-English papers, separating reviews from articles and the size of the citation window. Although contradictory results for these negligible effects might have been observed in particular measurement paths, they do not hold any overall effect in the multivariate regression framework. The application of Web of Science instead of Scopus has contradictory results, whose reason is still to be investigated.

Outlook

We are currently extending the current analysis by (1) refining the measurement decisions, (2) including further measurement decisions, (3) computing the PP(top10) indicator and (4) drafting a Bayesian model to show how measurement paths in bibliometrics carry considerable consequences for the analysed entities and how "model-based" descriptive statistics might help to alleviate these.

Abstract

The paper aims to analyse the major changes in publication practices occurred in Social Sciences and Humanities in the Italian Academia after the implementation and introduction of two new procedures aimed at improving quality of research in Italian academia i.e. a Performance Based Funding System and a new recruitment mechanism for academic staff based on national habilitation. The analysis is carried out by analysing: 1) data on the overall scientific production of professors and researchers holding a permanent position in Italian Universities at a given point in time looking back at their production in the last 15 years (hereinafter "Loginmiur" database); 2) the data collected during the two research assessment exercises carried out by ANVUR in 2012 and 2016 (hereinafter VQR), referred to the period 2004-2014, which represent a specific subset of that production. The main result emerging from the analysis is that the share of journal articles published by scholars in SSH has progressively increased (particularly from 2012 which is the year in which both new procedures were firsly implemented) and, nonetheless, monographs seem to retain a central role in all SSH area. The introduction of the assessment policies seems to have influenced the choice of publishing in those journals defined by ANVUR as "A class". Finally, the score achieved by the research outputs assessed in both VQR exercises prove to be related to the publication's typology.

Introduction

The paper aims to investigate the changes occurred in the publication practices in the SSH after the introduction of two new procedures aimed at fostering research quality in Italian academia i.e. the Research Quality Assessment (hereinafter VQR, Valutazione della Qualità della Ricerca), that is a performance based research funding system (Hicks 2012), and a new recruitment mechanism for academic staff called National Scientific Habilitation (hereinafter ASN) introduced by the Ministry of Education. Our paper wants to understand the response, in terms of publication choices, to the introduction of new rules and incentives in the Italian academia and to the need of meeting new requirements.

Both the measures have been introduced by the Ministry of Education and University (hereinafter MIUR) in 2012.

The Research Quality Assessment exercises (VQR) are aimed at evaluating the research outcomes of state-financed Universities and Research Institutions and at providing an up-to-date assessment of the state of research in the various scientific fields, in order to promote the improvement of research quality in the assessed institutions. Its results are used by MIUR to allocate the merit-based share of the *Fondo di Finanziamento Ordinario* (FFO) – the financing fund of the Italian university system. According to the Law 232/2016, VQR exercises have to be carried out every five years. To the time we are writing, ANVUR has already completed two rounds of assessment, one covering the publication years 2004-2010 (hereinafter VQR1) and the second covering the publication years 2011-2014 (hereinafter VQR2). A new exercise, covering the years 2015-2019, is going to be issued by MIUR by March 2020.

The two VQR exercises adhered to broadly similar rules and methodologies. All research outputs submitted in the SSH areas[i] were assessed using peer review: each research output was assigned to two members of the panel of experts (GEV member). Panel members had to choose independently two external experts (even three in case of disagreement) who assessed the paper following three criteria (relevance, originality and internationalization in the first VQR; originality, methodological rigor and attested or potential impact in the second VQR).

Almost simultaneously to the introduction of PRFS, the Ministry of Education introduced a new hiring procedure for academic professors in which the National Scientific Habilitation (ASN) is a necessary requirement to apply for permanent positions of Full and Associate Professor in Italian Universities.

In order to get the ASN, candidates have to reach minimum values of the indicators of scientific qualification defined by the Ministry of Education (MIUR) and proposed by ANVUR. Indicators of scientific qualification in Social Sciences and Humanites: number of journal articles and book chapters published in the last 10 years; number of journal articles published in A-class journals in the last 15 years; number of books published over the last 15 years of career. In order to calculate such indicators in humanities and social sciences, ANVUR rates journals in two lists (A-class journals and scientific journals).

The hypothesis behind our analysis is that the introduction of Performance Based Funding Systems (PRFS) and in general of procedures that push academics towards research of higher quality, such as ASN procedure, may induce changes (including unintended ones) in the publication practices of the affected scientific communities (Moed, 2008, Jiménez-Contreras, De Moya Anegón, & López-Cózar, 2003). The impact on publication practices may depend (at least in part) on the characteristics of the scientific communities involved.

In the SSH, scholars are often more affected by the national context, even in the selection of research topics; moreover, they tend to publish – besides journal articles – book chapters, books and works belonging to niche typologies (Lariviere *et al*. 2006, Nederhof 2006, Bolton & Kuteeva 2012, Kuteeva & Airey 2013).

Past experience shows that the introduction of research assessment processes has frequently influenced publication practices, particularly by fostering publications in indexed journals (Leite, Mugnaini, & Leta, 2011; Paji, 2015), in addition to increasing the use of English (Li and Flowerdew 2009; Li 2014). In other words, research evaluation tends to steer researchers in SSH towards modes of dissemination (if not production) of knowledge closer to those usually considered as more typical of STEM disciplines.

What emerges from the literature (Aagard 2015) is that the incentives introduced by research evaluation systems have a considerable impact even when the effects on funding are limited, as it happens in Norway (where evaluation results determine 2% of the funding). Therefore, we may expect a greater impact in those countries where these effects are stronger, such as in Italy (where evaluation results determined, in 2018, 19% of the overall ordinary funding of universities).

The existing literature suggests that research evaluation systems actually impact publication practices: Kulczycki *et al*. (2018) highlighted the sharp reduction of the number of monographs in Poland between 2011 and 2014, as a result of the introduction of an evaluation system which discouraged from publishing research outputs other than articles in indexed journals. By comparing the situation of eight EU countries, they found that in the same period the share of monographs and journal articles remained stable in Denmark, Finland, Norway and Flanders (the share of journal articles being much higher than in Italy).

In order to understand the changes occurred in SSH publication practices in Italy, we use two sources of data: 1) the dataset of publications of Italian scholars in service at the beginning of 2018, looking back at their production in the last 15 years (2003-2017); 2) database of research poutputs submitted to the two VQR exercises. The analysis focuses on the publication channels favoured by scholars in SSH, and on the presence (or absence) of the research outputs submitted for evaluation in the main international databases (Web of Science and Scopus). We also try to understand whether the introduction of these new procedures have actually achieved the intended effects i.e. fostering research quality looking at the scores obtained in both VQRs.

Scientific production in SSH area: 2003-2017

The first question we try to address is whether the introduction of research assessment in the Italian university system has had unintended effects, such as that of increasing the overall number of publications, as happened in UK after the introduction of RAEs (Moed 2008, Moya et al. 2015) , and especially whether it has influenced the choices of publication channels: our expectation is that specific publication typologies have become more or less frequent depending on whether or not they have been considered eligible for the evaluation procedures

We present and analyse data regarding research outputs published between 2003 and 2017 by all professors holding a permanent position in Italian universities in February 2018, looking back at the last 15 years of their career. Those data have been extracted from the national database containing all the publications of Italian scholars (henceforth denominated Loginmiur).

Looking at the total number of publications by year, we note that the effect of boosting the number of publication do not happen in Italy. In fact research production have an hump shape that describes the typiucal research life cycle of academics: the number of publuication grows at the beginning of the career, reaches a peak and hence decreases (Figure 1).

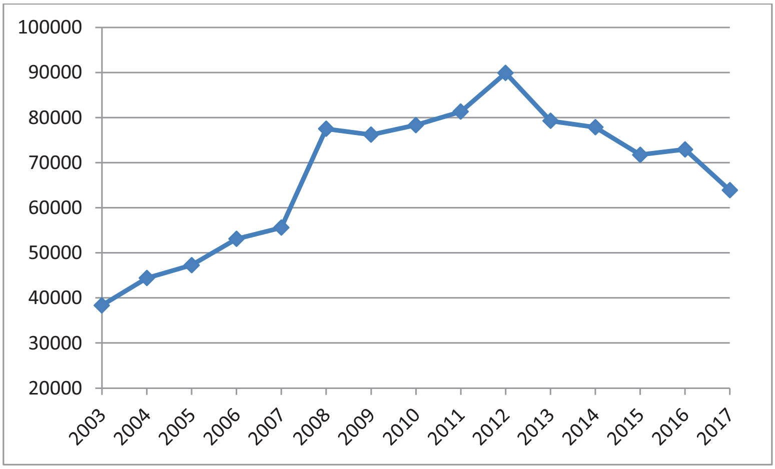

Figure 1. Number of publications by SSH Italian academics in service as of February 2018 per year (2003-2017).

In order to understand the changes occurred in publication practices regarding the research output typologies, we calculated for each year the share of publications in the following typologies: monographs, journal articles, book chapters, conference proceedings and a residual category containing minor and niche publication typologies.

At aggregate level (i.e. for all SSH disciplines, last image of Figure2) data show a significant increase of the percentage of journal articles after 2012, a minor decrease of both monographs and proceedings. The increase of journal articles is particularly marked in the area of Economics and Statistics, where the percentage almost doubled, but is still significant in the other areas (except Architecture and Law). On the other hand, the share of monographs decreased in the 15 years-period in all areas (its percentage decreases from 8% in 2003 to 5% in 2017), and shows a fluctuating trend. A peak in the share of monographs is reached in 2012 in all areas, probably as a result of the first ASN round. Comparing the percentage variation in 2003-2011 with that of 2012-2017, we find a slight reduction of the share of monographs (from 6,2 to 5,6%).

The percentage of book chapters grows in almost all areas (the aggregate percentage goes from 32% to 34%); the highest increases occur in Law and Philology, Literary studies, Art History, while in Economics and Statistics we register a steep decrease from 29% to 21% and in Political and Social Sciences a slight decrease (see Figure 1).

At aggregate level and in all single SSH disciplines, we also see clearly that the share of publications in outlets not relevant for ASN (i.e. not computed in the indicator valid for ASN) sharply decline after 2012.

We analyse publication data as aggregated according to the indicators required by the Ministry to access the Habilitation procedure (detailed in the Ministerial Decree n. 120/2016). The habilitation is granted on the basis of an evaluation of the candidate’s titles and publications; in order to have access to this evaluation phase, applicants are required to reach fixed thresholds for at least two out of three indicators of scientific qualification.

The first indicator defined by the Ministry refers to journal articles (published in the so-called “scientific journals”, according to ANVUR classification) and book chapters[ii]. The second indicator refers to articles published in “A class” journals (representing a subset of scientific journals)[iii]. The third indicator refers to books and includes (besides monographs) niche typologies such as critical editions, critical editions of excavations, publication of unedited sources, and so on.

Figure 3 shows the distribution of publication typologies valid for the ASN indicators between 2003 and 2017. In this period, a sharp increase of the share of journal articles and book chapters can be observed: at aggregate level, it grows from 58.2 to 75.9% of the total scientific production, the same trend being reflected in all areas.

If we compare the percentage increase between 2003 and 2011 with that between 2012 and 2017, we find that neither the introduction of the ASN (firstly launched in 2012) nor the announcement of the VQR (whose public Call had been issued in November 2011) significantly accelerated a process which was, as a matter of fact, already ongoing. Considering all areas, indeed, the share of articles and book chapters increases of 11 percentage points in the decade before 2011, with respect to an increase of 6 percentage points in the six-year period after 2012.

However, the introduction of ASN, although not affecting the choice of publishing a journal article, seems to affect the choice of which journal researchers publish in. In fact, looking at the evolution of publication in the so-called “A-class journals” (see again Figure 2), we find a percentage increase (at aggregate level) of 6 percentage points of the share of those kind of publications between 2012 and 2017, with respect to a constant share of publications in class A journals in the period before 2012.This increase is widespread in all SSH area, although it is not homogenous across areas: the increase of the share of A-class journal articles is particularly remarkable in the areas of History, Philosophy and Education (from 8,6 to 14,5%) and Economics and Statistics (from 9,8 to 22,2%), and less so in Architecture (from 5,5% to 8%), Antiquities, philology, literary studies, art history (from 9,7 to 12,3%), and Law (from 17, 9 to 22,4%).

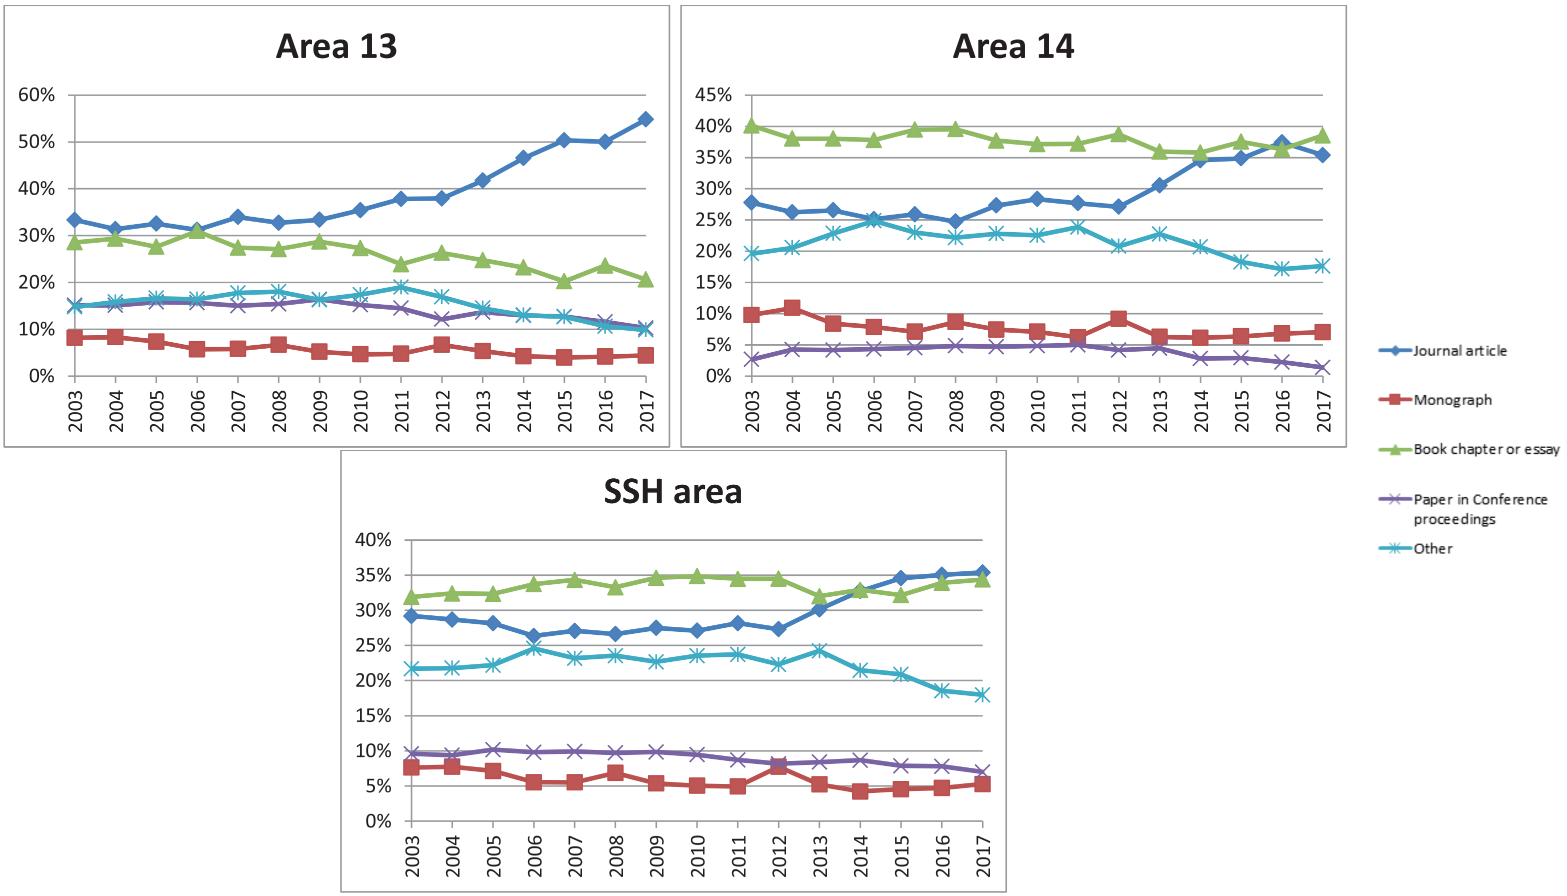

Figure 2. Percentage of publications in SSH (per year, publication typology and subject area)

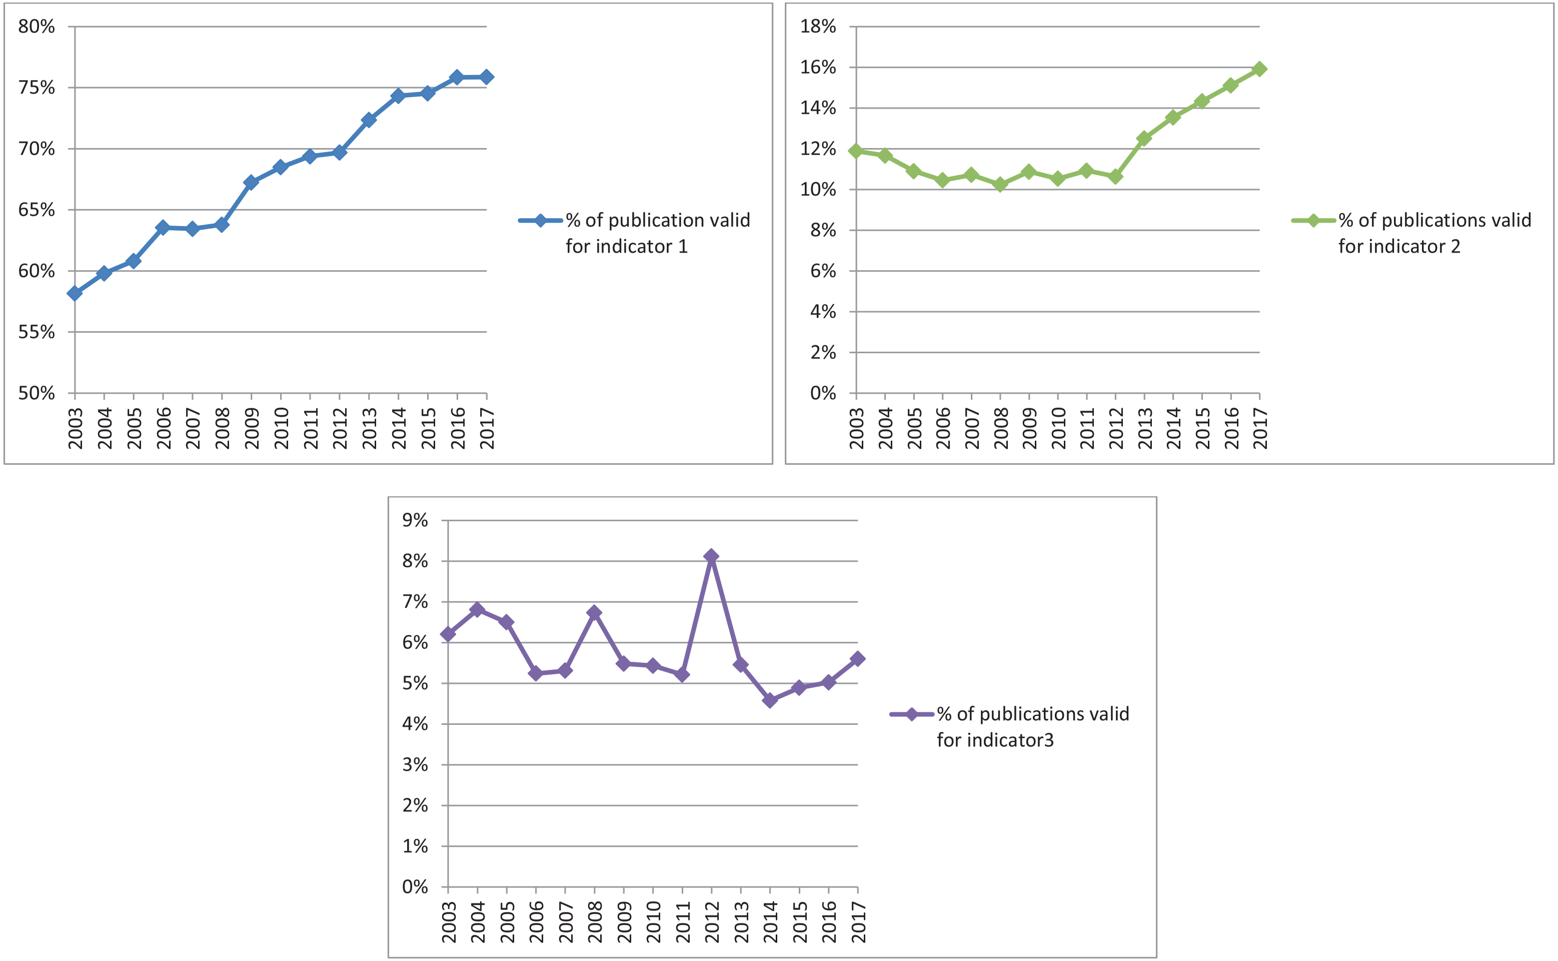

Figure 3. Share of publications in SSH disciplines valid for the three ASN indicators

Typologies of research outputs submitted for VQR1 and VQR2

In this section we look at the changes in publication outlets using VQR data. VQR database represent a subset of the publications taken into account in the previous paragraph. In each assessment exercise, institutions are in fact asked to submit for each affiliate researcher a selection of research outputs (three in VQR1 and two in VQR2) deemed as the best in terms of scientific quality.

We replicate the previous analysis on this subset in order to understand whether the patterns elicited for the entire set of publications persist (or not) once we consider only the best ones, in order to detect possibly new phenomena.

Both in VQR1 and in VQR2, monographs represented a large share of the research outputs submitted by Italian scholars, the percentage being 25% and 20% for VQR1 and VQR2 respectively (see Table 1). The higher percentages emerging from VQR data with respect to Loginmiur data (the share of monographs out of the total scientific production in the same period equal to 6%) may be explained by the fact that, according to the literature, scholarly monograph is deemed to be the most high-profile research output in almost all the SSH disciplines (Thompson 2002; Verleysen-Ossenblok 2017): hence, it is predictable that monographs are overrepresented among outputs selected as the best ones in a given timeframe.

Scholarly monographs, therefore, retain a central role in all SSH areas, except in that of Economics and Statistics, whose publication practices are closer to those of STEM disciplines. According to VQR2 data, the highest share of monographs is to be found in the area of History, Philosophy and Education (27,1%).

Despite the large share of monographs submitted for evaluation, a comparison between VQR1 and VQR2 data shows a decreasing percentage in all SSH areas. The reduction is more significant in the areas of Political and Social Sciences (-10,8%), and of History, Philosophy and Education (-7,1%), faced to Law (-1,9%) and Architecture (-2,5%). The share of book chapters decreased in almost all areas except Philology, Literary Studies, Art History and Political and Social Sciences, where it remains stable.

The share of journal articles submitted for evaluation in both VQRs is much lower in SSH disciplines than in STEM disciplines. In STEM areas, indeed, the percentage of journal articles out of the total of submitted publications is around 90% on average, much higher than in SSH areas where the percentage, at aggregate level, ranges between 34% in VQR 1 and 44% in VQR2. Factors such as the language and the orientation towards a “local” scientific debate may explain this difference. The share of journal articles submitted for evaluation increases between the two evaluations in all areas (+10% on average). Namely, in VQR1 monographs and book chapters are the most recurring types of publication in all SSH areas, except Economics and Statistics; in VQR2 journal articles are, on the contrary, the most widely used publication channel. The highest percentage increases are found in the areas of History, Philosophy and Education (+11,8%) and Political and Social Sciences (+12,7%) and Economics and Statistics (+10,9%). Indeed, the latter area is exceptional as its researchers submitted the highest share of journal articles in both VQR; in VQR1, in particular, this share reaches 62,5%, and is thus much higher than in any other SSH discipline. This is due to the peculiar characteristics of the area, that is closer to the STEM disciplines in terms of publication behaviour. It is very likely that also the assessment criteria chosen by the panel of experts, relying on bibliometric indicators, have been a contributing factor.

Source: authors' elaboration on ANVUR data

Monographs obtain an higher average score than all other publication typologies (statistically significant at 1%[iv]), in both VQR exercises in the following areas: Architecture; Philology, Literary Studies and Art History; History, Philosophy and Education; Law (see Table 1). Economics and Statistics is again an outlier, as journal articles get on average scores much higher than monographs in both VQRs (0.52 vs 0.11 in VQR1; 0.62 vs 0.23 in VQR2). In Political and Social Sciences the scores obtained by monographs and journal articles are similar (the difference is not statistically significant), yet they are higher than those assigned on average to other publication typologies. We can hence conclude that in almost all the "pure Humanities disciplines" monographs continue to represent the outlet to which researchers entrust the more relevant contributions/findings. Differently, both in Economics and Statistics and in Political and Social Sciences, researchers seem to behave in this respect more similarly to STEM disciplines, choosing journal articles as an important publication outlet for their best research.

Table 2. Quota of journal articles indexed in bibliometric databases submitted for evaluation in VQR1 and VQR2 by area.

Source: authors' elaboration on ANVUR data

As for journal articles, a specific analysis can be carried out with regard to those published in journals indexed in the main international databases (i.e. Clarivate WoS and Scopus). By comparing the data of VQR1 and VQR2 (see Table 2), there is evidence of a considerable increase of the share of publications indexed in WoS and Scopus in all SSH areas. The highest increases are registered in Architecture (+7%), Economics and Statistics (+21%) and in Political and Social Sciences (+9%), while the lowest is reported for Law (+0.5%). This is in line with two general trends observed also elsewhere: a trend to favour journals (including international journals) as publication channel, which determines an higher degree of coverage of publications belonging to SSH in the main databases and a trend of increasing coverage of SSH disciplines journals in the international databases. Therefore, it is not easy to separate the impact of these trends from that produced by the introduction of research evaluation practices, which may have affected the habits of Italian scholars, as happened in other countries (Leite, Mugnaini, & Leta, 2011, Paji, 2015).

VQR data also allow to examine the coverage in the two main databases of the subset of publications selected to be submitted for evaluation in SSH. The degree of coverage varies of course depending on the research field, but the journals where SSH research is published are more likely found in Scopus than in Clarivate WoS (much as it occurs internationally: see Norris & Oppenheim 2007).

The WoS coverage is widest for the area of Economics and Statistics (40,3%), followed by History, Philosophy and Education (7,2%). We find higher percentages of publications submitted for evaluation and indexed in Scopus; again, their share peaks in the areas of Economics and Statistics, Political and Social Sciences , History, Philosophy and Education. In all areas, however, we find an increase of the share of publications indexed in international databases between VQR1 and VQR2.

Conclusions

Our analysis, carried out using two unique databases of research output in SSH, comes to the following conclusions. Italian academics did react to the new procedures in order to meet new requirements. The introduction of the research assessment policies and new hiring procedure turns out to have influenced the choice of publication outlets; more particularly, it increased the share of articles appearing in journals defined by ANVUR as "A-class". Nonetheless, monographs retain a central role in all SSH disciplines except for Economics and Statistics. As a further result of the analysis, it can be noted that the score achieved by the monographs and journal articles in both VQR exercises are higher than those of any other publication channel. Henceforth, we may conclude that researchers in SSH entrust their best research findings to these two types of publication.

[i] In our analysis we use the definition used in VQR and SSH areas comprises: Architecture (area 8.1 in VQR); Philology, Literature Studies and Art History (area 10 in VQR); History, Philosophy, and Education (area 11.a in VQR); Law (area 12 in VQR); Economics and Statistics (Area 13 in VQR); Political and Social Sciences (area 14in VQR). In VQR, a panel for each of the mentioned areas was appointed.

[ii] The first indicator includes further publication typologies such as: law case notes (provided they are published in journals classified as "scientific"), entries in dictionaries or encyclopaedias, forewords, afterwords, papers conference proceedings (provided they are published in journals classified as "scientific" or associated to an ISBN code).

[iii] The second indicator also includes law case notes (provided they are published in "A-class" journals).

[iv] A T-Tests for pairs of typology shows that monographs always got a statistically significant higher score than any other typology. T-tests results are available on request.

Measuring changes in country scientific profiles: the inertia issue

Abstract

The literature comparing the scientific profiles of high-income research-intensive countries and those of developing and emerging countries find a higher degree of inertia in the case of the former. This diagnosis may however be biased by the size of the country and the maturity of the research system. This contribution shows that the volume of publications has a decisive influence on the inertia that is measured. The demonstration is based on the computation of distances between the specialization indexes overtime at the finest level of the Web of Science classification (175 categories, excluding Social Sciences and Humanities) and for 80 countries representing over 95% of world publications. These distances, which measure changes in specialization, prove to be highly sensitive to publication volumes. We therefore propose to cancel out the volume effect, at least partially, by computing a residual inertia. Once the size effect has been neutralized, the evolution measured by the residual distance reveals very different dynamics of the scientific profiles among countries.

Introduction

The scientific profile of a country results from the interactions between the global generation and diffusion of knowledge and the domestic research system. Changes in this profile are driven both by the dynamics of science and by public policies, including the allocation of resources to different disciplines and research issues. Public support for certain specialized institutions or the financing of research programs influence the disciplinary profile of countries.

Over the long term, as an economy develops and investments in research grow, the scientific system matures and diversifies, becoming less strongly specialized in a small number of research fields and disciplines (Archibugi and Pianta, 1991). Emerging countries that have been investing heavily in their scientific systems for several decades are therefore undergoing a process of diversification. Their scientific profile does, however, still remain much more specialized than that of the high-income, research-intensive countries. The evolution of the scientific profile of China over the last few decades illustrates these dynamics. The country has increased its scientific publications very rapidly and has at the same time somewhat reduced its specialization in chemistry. A number of European Union members in a catching-up phase since the 1990s have also experienced a substantial evolution of their scientific profile (Peter and Bruno, 2010; Campbell et al., 2013). Medium to long term bibliometric analyses have pointed to the much more dynamic scientific profiles of emerging countries as opposed to research-intensive, high-income countries (Yang et al. 2012, Radosevic and Yoruk, 2014).

The opposition between dynamic scientific profiles in emerging countries and inert profiles in research intensive countries is at odds with the idea that the latter strive to advance the scientific frontier. Moreover, since the beginning of the century, the development of the scientific system has been recognized as a major policy area in order to promote knowledge-based economies. In this perspective, in many countries research funding has been increasingly based on the prospective impact of research on invention, innovation and the economy more generally. This trend has been reinforced by the emphasis public policies have put on the need for scientific research to contribute to solving societal challenges. Indeed, this objective may lead to specific funding schemes and research programs to tackle multidisciplinary issues.

Scientometrics may not be able yet to clearly evaluate societal impact as the impact of scientific contributions on various sectors of society (Bornmann and Haunschild, 2017), which entails generating new indicators from new data sources. Scientometrics can however measure the capacity of different countries to start new endeavours and refocus their research system on promising fields. In its study of the French innovation system, for example, the OECD (2014) stressed that the scientific profile of France did not seem to respond to the priorities set by public policies. The OECD report measured the "inertia" of the French scientific profile with the cosine distance between 2000 and 2011, on the basis of the Web of Science subject categories. This type of analysis does not take account of the fact that the development of a scientific system generates a certain degree of inertia that is at least partly due to the growth in the volume of publications. The volume of publications is only partially endogenous to the implementation of a scientific development strategy and is also a manifestation of the size of the country (population, GDP, etc.). In other words, the size of a country has a mechanical impact on the apparent inertia of its research system. The role of size has already been noted in studies dealing with countries' scientific profiles on their dynamics (Peter & Bruno 2010; Almeida et al 2009). The impact of size has however not been quantified and there does not exist a measure of the dynamics of scientific profiles correcting for the influence of size.

The contribution of this paper to the literature on the dynamics of scientific profiles is twofold. Based on an aggregate measure of the evolution of country scientific profiles, it first shows how the volume of a country's scientific production impacts the measure of changes in those profiles. It then designs a measure of the dynamics of scientific profiles that corrects for the size bias.

The rest of the paper is organised as follows. Part two goes over the usual indicators for measuring scientific specialization and presents the data. Part three shows the ranking of countries in terms of the dynamism of their scientific profile. Part four demonstrates the influence of the size and complexity of the scientific system on its ability to change over time. It also designs a measure of the dynamics of specialization that corrects for the identified size bias. The conclusion summarises the results and discusses policy implications.

Method and data

The question appears simple at first sight. We need only to quantify the specialization of a country and measure its change between two years that are quite far apart from each other in order to ascertain its degree of inertia or structural change concerning this specialization. In fact, however, the analysis encounters difficulties in providing a precise definition and measuring specialization and its change.

The disciplinary structure of the publications may constitute a first measurement of specialization.

$$PD_{i,t}^{j} = \frac{\#\ of\ publications\ country\ i\ in\ scientific\ area\ j}{\#\ of\ publications\ of\ country\ i}$$

The disciplinary composition of a country's publications does not allow a comparative analysis to be made between countries or with a reference geographic area, however. Some disciplines might represent a large share of publications in all countries, or in certain groups of countries. In this respect, the indicator of this share needs to be normalized,

The specialization index (Activity Index, AI) provides this normalization.

$$AI_{i,t}^{j} = \frac{PD_{i,t}^{j}}{PD_{ref,t}^{j}}$$ [i]

AI is a double ratio and analysing the change in specialization therefore comes up against two problems. First, the fact that we cannot determine the reasons for a variation in a simple manner, as it may be due to variation in one or several components of the formula. Also, changes in the AI are sensitive to the volume of publications of the countries: the higher the world share of a country, the more that country influences the world structure of publications, which mechanically tends to make that country appear more inert than smaller countries.

Measurement of the change in scientific profile

To measure the change in the scientific profile, we need to assess how the distribution (specialization) vectors vary over time. This consists in putting together the information from the initial and final values in order to obtain an indicator of the change between the two vectors. These measurements are broken down into two main groups: measurements of association or similarity and measurements of distance (metric or not) or dissimilarity.

An appropriate compound measurement must possess at least two properties.

1) Invariance to the aggregation level. Dividing a category in two must not modify the value of the measurement when the change in each of the two sub-categories is identical to the change in the initial category.
2) Invariance to the addition of a category of negligible weight. The addition or deletion of a category of a small weight should modify the value of the measurement only marginally.

As well as being easy to use, the Manhattan distance satisfies these requirements due to its linear structure on positive values:

$$D_{i,X}^{Manhattan} = \sum_{j=1}^{n} |X_{i,t}^{j} - X_{i,\tau}^{j}| \qquad with\ t > \tau\ ,\ X_{i,t}^{j} = PD_{i,t}^{j}\ or\ X_{i,t}^{j} = AI_{i,t}^{j}$$

In the specific case of the use of the AI for a country F:

$$D_{F,AI}^{Manhattan} = \sum_{j=1}^{n} |\frac{PD_{F,t}^{j}}{PD_{W,t}^{j}} - \frac{PD_{F,\tau}^{j}}{PD_{W,\tau}^{j}}| \qquad with\ t > \tau\ \ (1)$$

The formula for the final year of the analysis period becomes:

$$\frac{PD_{F,t}^{j}}{PD_{W,t}^{j}} = \frac{PD_{F,\tau}^{j}}{PD_{W,\tau}^{j}} \frac{(1+g_F^j)}{(1+g_W^j)}\ (2)$$

with g_F^j the rate of growth of the share of discipline j for the country and g_W^j the rate of growth of the share of discipline j for the world, we can write

$$D_{F,AI}^{Manhattan} = \sum_{j=1}^{n} |\frac{PD_{F,\tau}^{j}}{PD_{W,\tau}^{j}} \frac{(1+g_F^j)}{(1+g_W^j)} - \frac{PD_{F,\tau}^{j}}{PD_{W,\tau}^{j}}|$$

After simplification:

$$D_{F,AI}^{Manhattan} = \sum_{j=1}^{n} |\frac{PD_{F,\tau}^{j}}{PD_{W,\tau}^{j}} \frac{(g_F^j - g_W^j)}{(1+g_W^j)}|$$

We define:

$$\alpha^j = \frac{(g_F^j - g_W^j)}{(1+g_W^j)}$$

where α^j is the dynamism of the share of discipline j for country F relative to the world.

The distance of the specialization between two dates can therefore be expressed as the product of the AI of the initial year with the relative dynamism coefficient.

$$D_{F,AI}^{Manhattan} = \sum_{j=1}^{n} |\frac{PD_{F,\tau}^{j}}{PD_{W,\tau}^{j}} \alpha^j|\ (3)$$

Computation requires a stable classification of research fields as the appearance of new disciplines distorts the analysis in terms of specialization. This is all the truer when the subject of the new discipline was previously divided between several disciplines in the classification prior to the change. There will therefore be an automatic decrease in the activity in those fields and the appearance of a new specialization without a counterpart in time, with the result being a false structural change in specialization[ii].

Data

Computations were performed on 176 WoS subject categories (SSH are not included). The data correspond to the years 1999/2001 and 2011/2013[iii] for 80 countries representing over 90% of world publications. Fractional counts were used. Complementary sources were used for variables such as the per capita income (purchasing power parity) and population (World Bank and Eurostat for the data for EU-28,). See Appendix 1.

Ranking of countries based on the dynamics of their scientific profile

Table 1 shows that countries with a mature scientific system experience little change in their profile, contrary to countries producing a smaller volume of publications.

Table 1: Manhattan distance for the Activity index between 1999-2001 and 2011-2013

Country	Manhattan Distance	Rank Manhattan
EU28 +	30.21	1

High-income countries thus seem to have stable scientific profiles, while emerging countries exhibit more dynamic profiles. This result is similar to the conclusions reached by Radosevic and Yoruk (2014). In order to conclude whether this stability is actually inertia, our next step is to measure the potential impact of size and related characteristics of national scientific systems.

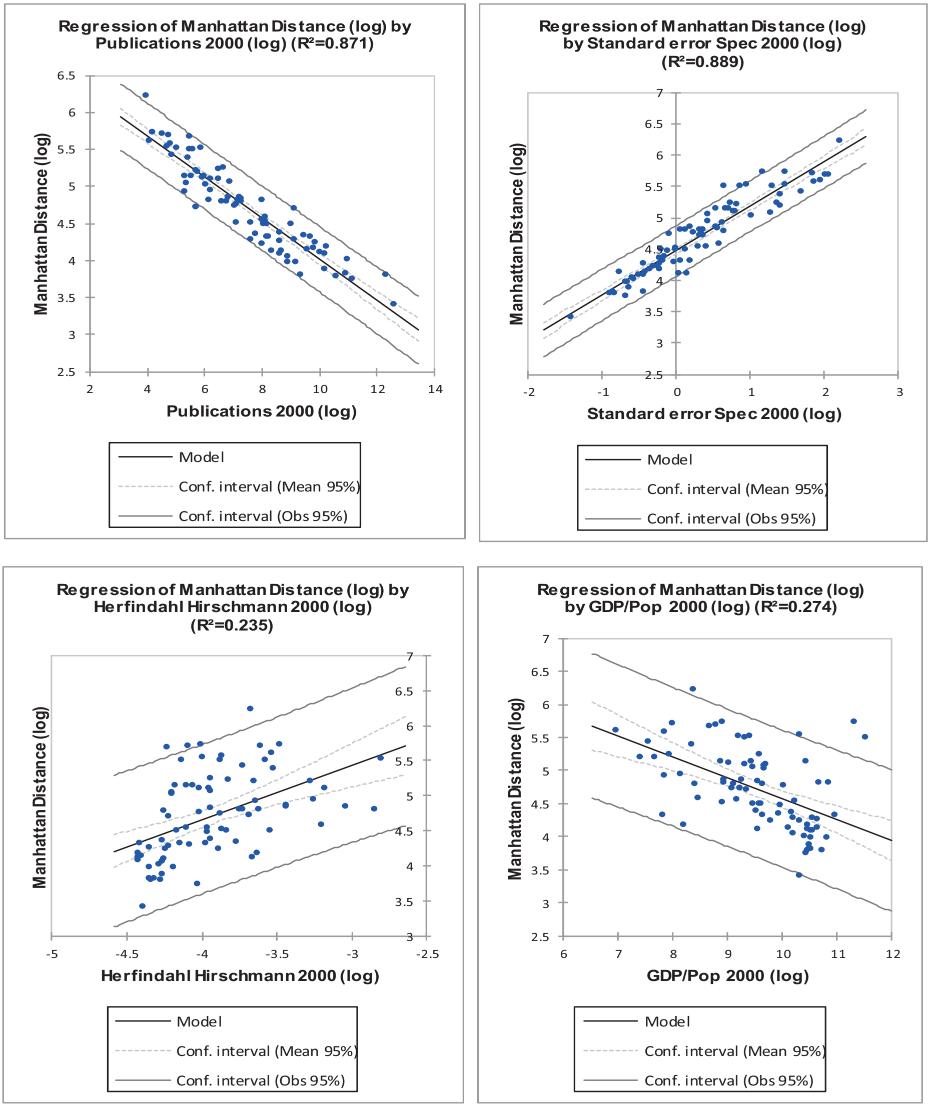

Figure 1: Manhattan distance and characteristics of the scientific systems

Size in terms of volume of publications can impact the Manhattan distance through two channels. The first one is direct: a country that produces a large volume of publications, all other things being equal, requires very significant changes in order to modify its profile substantially. Conversely, in a country with a small volume of publications, even marginal increases in the number of publications will modify its specialization substantially. The second channel is indirect: a country that produces a very large volume of publications covers a broad spectrum of disciplines and has a balanced specialization, whereas a country with a limited number of publications can cover only a restricted range of research fields. In the former case, an increase in the publications in a particular research field changes the specialization only marginally, whereas in the latter case, it might be changed radically.

Moreover, size influences two other characteristics of national scientific systems: the degree of specialization and disciplinary concentration. The degree of overall focus or specialization of countries is measured by the standard deviation of the specialization indicator over the 176 subject categories. High dispersion means that the scientific system is focused on a number of fields, while low dispersion means that the country has a less contrasted profile with similar research capacities in many fields. In high-dispersion systems, a small variation in the number of publications in a non-specialization field can cause substantial change in specialization.

Disciplinary concentration of scientific systems may also be measured. We calculate the Herfindahl-Hirschmann index based on the share of each subject category in total publications in 2000. High concentration is considered as an indicator of contrasted specialization and low concentration as an indicator of diversification.

Finally, the volume of publications itself is not totally exogenous since it tends to increase with the development and maturation of the scientific system. For an approximation of the level of development of the scientific system, we use the level of income per capita on a purchasing power parity basis. Obviously, using this indicator as a proxy of the development of the scientific system is not enough. Per capita income depends, among other things, on the productive structure of the country. For example, the oil-producing countries have high per capita incomes (depending on oil price cycles), but their scientific systems are far from having comparable depth and level of diversification to those of the developed countries.

The impact of the volume and disciplinary diversity of publications on the dynamics of specialization is tested through an analysis of the correlations between the Manhattan distance and four variables: volume of publications in 2000; dispersion of specialization by subject category; disciplinary concentration; GDP per head.

To obtain an overview and taking account of the collinearity between the variables that were used, we performed a Principal Component Analysis (PCA) followed by a typology based on Agglomerative Hierarchical Clustering (AHC).

PCA results

The PCA shows a single highly significant axis (67.7% of the total variability), thereby demonstrating strong collinearity between the variables chosen (Table 2 and Graph 2).

Table 2: PCA, Eigenvalues and correlations factors and variables

	F1	F2	F3	F4
Eigenvalue	2.705	0.701	0.465	0.129
Variability (%)	67.632	17.523	11.618	3.227
Cumulative %	67.632	85.155	96.773	100.000
Correlations				
Publications 2000 (log)	-0.875	0.387	-0.167	0.239
Standard error Spec 2000 (log)	0.904	-0.335	0.027	0.263
GDP/Pop 2000 (log)	-0.790	-0.273	0.547	0.050
Herfindahl Hirschmann 2000 (log)	0.706	0.604	0.370	0.015

The F1 axis opposes countries with high-income and a significant number of publications, and those with a very marked specialization profile (high specialization standard deviations) and disciplinary concentration.

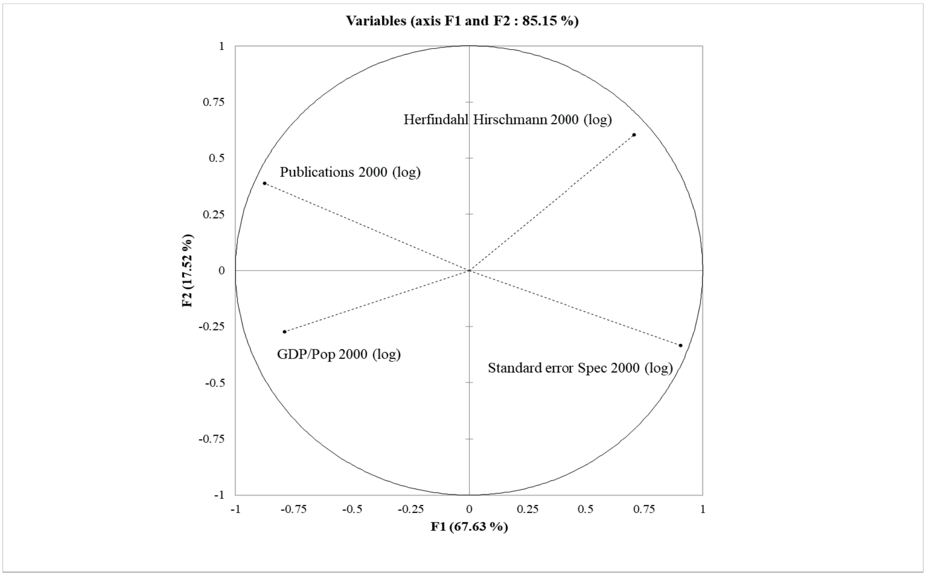

Figure 2: Circle of correlations

AHC results

The AHC produces four clearly differentiated groups (Table 3)

Table 3: AHC, a four-group typology

1	2	3	4
Germany	Argentina	South Africa	Saudi Arabia
Australia	Brazil	Algeria	Bangladesh
Austria	China	Bulgaria	Belarus
Belgium	Korea, Republic of	Cyprus	Bolivia, Plurinational State of
Canada	Hungary	Colombia	Burkina Faso
Denmark	India	Croatia	Cameroon
Spain	Iran (Islamic Republic of)	Egypt	Chile
United States	Mexico	United Arab Emirates	Costa Rica
Finland	New Zealand	Estonia	Ivory Coast
France	Poland	Iceland	Cuba
Greece	Russian Federation	Jordan	Ecuador
Ireland	Singapore	Lebanon	Indonesia
Israel	Slovenia	Lithuania	Kenya
Italy	Taiwan, Province of China	Luxembourg	Latvia
Japan	Czech Republic	Malaysia	Morocco
Norway	Turkey	Slovakia	Nigeria
Netherlands		Thailand	Pakistan
Portugal		Tunisia	Peru
United Kingdom		Uruguay	Philippines
Sweden		Venezuela, Bolivarian Republic of	Romania
Switzerland			Senegal
EU28 +			Ukraine
			Viet Nam

Table 4 presents the median values of the variables used in the PCA, according to the typology groups from the AHC. We note that Group 1 is made up of high-income economies and presents the highest median volume of publications, the lowest standard deviation of specialization, the lowest disciplinary concentration and the highest level of per capita GDP. At the other extreme, Group 4 is made up of developing economies which produce a small number of publications, have a very high standard deviation of specialization and disciplinary concentration, and a much lower level of development. The median Manhattan distance increases from group 1 to group

4: countries endowed with a diversified scientific system are those in which structural change measured by the Manhattan distance is the smallest.

Table 4: Medians* of the population by AHC group

	All	Group 1	Group 2	Group 3	Group 4
Manhattan (Distance)	**114.57**	58.49	84.36	162.11	187.54
# publications in 2000	**1 403.79**	12 867.19	4 653.92	406.03	264.31
Standart Error Specialization 2000	**1.33**	0.58	0.97	1.93	3.90
Herfindahl-Hirchmann Index	**0.01871**	0.01320	0.01921	0.01866	0.02930
GDP/Pop 2000	**14 732.48**	36 650.19	15 291.34	12 703.29	4 483.81

**: Preference was given to the median over the mean in order to avoid any bias due to extreme values. For example, Saudi Arabia is in group 4 despite a GDP comparable to that of developed economies.*

A normalisation of structural change

We build on the correlation observed in Table 4 to "normalise" the measure of structural change. We use the residuals from an equation that expresses the Manhattan Distance (MD) as a function of the volume of publications or characteristics of the scientific system as a structural change stripped of the volume effect.

$$MD_j = \alpha + \beta X_j + \mu_j$$
$$\mu_j = MD_j - \alpha - \beta X_j$$

The result of the estimation is presented in Table 5.

Table 5: Robust OLS of the Manhattan distance on volume

	Manhattan distance (log)
# Publications (fract) in 2000 (log)	-0.278***
	(0.0129)
Constant	6.795***
	(0.0999)
Observations	81
R-squared	0.871

Robust standard errors in parentheses
*** p<0.01, ** p<0.05, * p<0.1

Table 6 presents the ranks of the countries by increasing Manhattan distance and their ranks calculated using the residuals of equation in Table 5. Table 6 also classifies countries according to the extent of their change in specialization based on a univariate partitioning into 5 groups using the Fisher algorithm. It shows that the correction for size has a major impact on the evaluation of the dynamism of country specialization over the period.

Structural change is the greatest in Group 5. The United States stands out: it was initially ranked 4th (very strong inertia), while it ranks 79th after correction of the volume effect (strong structural change). The impact of the normalization is lower for the EU28: it was initially ranked 1st and comes in 58th after correction, joining the Moderate inertia group. Evolution is similar for Japan: it ranked 2nd and is 47th after correction, also in the moderate inertia group.

The disciplinary profile of a number of small high-income countries appears less dynamic after correction for size: Ireland, Norway. Other small high-income countries have quite inert profiles by both measures: Sweden, Belgium, Austria. France was initially ranked 3rd and is ranked 29th after correction, in the Strong inertia group. Italy experiences a similar change. Germany, which was initially close to France (rank 6), experiences a much larger change to rank 50 in the

Moderate inertia group. Spain and the UK are in the Moderate change group, like China. The UK experiences a similar very substantial change (from rank 10 to 75) but less dramatic than that of the US. At the opposite, after correction for size, a number of developing countries appear among the most inert ones, like Algeria, Vietnam or Iran.

Table 6: Manhattan Distance Calculated and Corrected.

Country	Rank Manhattan before correction	Rank Manhattan after correction	Group
Algeria	40	1	1 Very strong inertia
Ireland	23	2	
Viet Nam	52	3	
Sweden	5	4

Indonesia	76	78	
United States	4	79	
Brazil	39	80	
Bolivia, Plurinational State of	81	81	

Robustness

A change in the distance measure marginally modifies the correlations with the volume effect and our result. The Pearson correlation between the Manhattan distance and other distance measures (Canberra, Euclidean, Bray and Curtis, Khi^2, Cosines), particularly with the Euclidean distance, is very high and significant. Although correlation is less strong with the Cosines measure (similarity), the Spearman rank correlation is also very high. As a result, modifying the distance measure does not change the ranks of countries significantly. Concerning the volume, the Pearson correlation is very high and significant in all cases. A sensitivity analysis has been conducted (not reproduced); all correlations are significant at 1% level[iv].

Conclusions and further research

Designing an indicator of the evolution of national scientific profiles comes up against methodological difficulties. The indicator of changes in specialization is highly influenced by the structural characteristics of scientific systems, such as the volume of publications and disciplinary diversification.

Measuring changes in the specialization index in order to evaluate the dynamism of a research system or the impact of specific policies or research strategies is therefore not appropriate. This contribution has shown that it is necessary to implement a normalization procedure. The normalization that is proposed constitutes a reasonable approximation of the measurement of the medium to long term evolution of specialization by eliminating the size effect.

Country rankings are quite different when the specialization index is normalized. In particular, a number of research-intensive high-income countries show a substantially more flexible scientific profile. The normalized measure does on the contrary confirm that some high-income countries have a quite inert profile. After correction, developing countries have quite inert scientific profiles, while large emerging countries appear substantially more dynamic. Further research will be necessary to explain these differences in the impact of normalization. One objective would be to discuss the ability of countries to implement scientific strategies or to be able to develop emerging research areas.

[i] The Activity Index (AI), originally introduced in bibliometrics by Frame (1977) was constructed by Balassa (1965) for the analysis of the trade specialization (also known as Revealed Comparative Advantage indicator).

[ii] The most striking example is Nanoscience & Nanotechnology subject category in the WoS. It did not exist in 2000 and represented 0.69% of world publications in 2012. To eliminate the bias introduced by the appearance of this discipline, it would have been necessary to retropolate the nomenclature. We decided to accept this bias that particularly affects large specialized countries in 2012.

[iii] When it is mentioned 2000 (2012) in the text it is necessary to understand the average of the years 1999-2001 (2011-2013).

[iv] Rousseau (2018) proposed an alternative indicator, the F-measure. However, it actually presents similar problems with respect to the influence of publication volume (Pearson correlation is strongly significant, at 0.83, with $p<0.001$).

Highly cited references in PLOS ONE and their in-text usage over time

Abstract

In this article, we describe highly cited publications in a PLOS ONE full-text corpus. For these publications, we analyse the citation contexts concerning their position in the text and their age at the time of citing. By selecting the perspective of highly cited papers, we can distinguish them based on the context during citation even if we do not have any other information source or metrics. We describe the top cited references based on how, when and in which context they are cited. The focus of this study is on a time perspective to explain the nature of the reception of highly cited papers. We have found that these references are distinguishable by the IMRaD sections of their citation. And further, we can show that the section usage of highly cited papers is time-dependent: the longer the citation interval, the higher the probability that a reference is cited in a method section.

Introduction

Scientific publications are highly structured texts which incorporate specific properties related to their references. The accessibility of full-text publications has broadened up the possibilities for analysing citation behavior and the usage of referenced publications in bibliometrics. The objectives of this research-in-progress paper are highly cited PubMed papers in a corpus of the open access journal PLOS ONE[1] during the period between 2006 and 2017. As a highly cited PubMed paper, all papers (n=666) are taken into account which are cited in more than 100 PLOS ONE papers of our corpus. We call these highly cited papers *top-666*.

The main goal is to describe the highly cited papers based on extracted information from our corpus; this includes metadata of citing publications and citation contexts. So the information we gather is not from the full-text of the referenced publication, but the citing publications. On the paper level, we use the year of publication of the citing publication. On citation context level we use information about the sections based on the IMRaD scheme[2] which is "the most used standard of today's scientific discourse" (Sollaci & Pereira, 2004). As a second distinguishing feature, we examine the co-citation count on the citation context level. With the latter information, it is possible to investigate how a paper is perceived over time based on the citation interval. The citation interval is the time distance of the citing paper to the time of publication of the reference. With this information, we are able to describe the top cited references based on how, when and in which context they are cited. We use this information to describe the "citation history" of a specific cited object over time.

Having a deeper understanding and methodology for the usage of gathered information from citations based on full text is, on the one hand, helpful to understand the temporal citation

[1] https://journals.plos.org/plosone/

[2] i.e. Introduction, Method, Results, and Discussion

patterns of references, on the other hand, the information can be used to build better tools for information retrieval systems for suggesting related research literature (e.g. Huang et al., 2015).

In our study we will address the following research questions:

- RQ 1: In which IMRaD section are the top-666 references cited?
- RQ 2: How is the proportion of concrete IMRaD sections evolving over time?
- RQ 3: Is the number of co-citations on citation context level declining when the citation interval is becoming longer?

Related Work

Citations are an important parameter of connectivity of related research works. A lot of studies have focused on analysing citations for different purposes ranging from assessment of the quality of an article to tracing the flow of ideas on a topic. Sugiyama et al. (2010) have suggested that there could be two kinds of citation analysis: (1) Citation Counts and (2) Citation Context Analysis. They argue that citation context analysis could be a better approach to determine the influence of a research article. Unlike simple counts, citation context analysis identifies the contextual relationship between citing research articles and referenced articles by applying various NLP and Machine Learning approaches (Hernández-Alvarez & Gómez, 2016). It processes the text of articles, particularly that portion where it cites another article. This is called citation context, i.e. the sentence where a specific reference is cited. Relatively few studies have been carried out on citation context analysis.

Some researchers have performed a sentiment analysis by incorporating the citation context with the subjectivity analysis of citations (Athar & Teufel, 2012; Abu-Jbara et al., 2013; Athar, 2014). In a recent work, Bertin et al. (2016) have used the linguistic patterns to analyse the citation context and its location in the IMRaD structure of a research article to determine the recognition of citer motivation (Teufel et al., 2006). Another work by Small (2018) has studied the phenomenon of highly cited research articles based on citation context. They have examined citation context for linguistic patterns which are associated with different types of referenced research articles. As types, they consider method and non-method publications.

Boyack et al. (2018) have analysed the in-text citation characteristics in the larger dataset of Elsevier full-text journal articles and PubMed Open Access Subset articles. They have identified that all fields such as references, sentences, in-text citation numbers per article have increased over time. They also found that highly cited publications are often cited only once per publication. An et al. (2017) have carried out a study to identify the characteristics of highly cited authors on the basis of citation location and contexts using NLP techniques. They have worked on the ACL Anthology dataset (Bird et al., 2008). Atanassova & Bertin (2016) investigated positions of in-text citation in IMRaD structure regarding the age of cited papers.

Similar to Boyack et al. (2018) and Bertin et al. (2016), we search for patterns in the position and the linguistic context references are cited. But in opposite to them, we change the perspective from the citing publication to the referenced publication. Analogue to Small (2018), we are interested in retrieving information for specific highly cited references from their citation context. But unlike Small, our goal is not the classification of references based on a predefined schema. We want to provide a basis for a comprehensive analysis of the references based on the citation contexts. Additionally, we introduce time aspects in respect to citation interval to the analysis of highly cited references.

Methods

Description of the Dataset

Our research object is a corpus of citation contexts of highly cited references. Each context consists of the sentence in which the citation occurs. For all sentences, we add information about the citing publication and basic information (incl. publication year) of the referenced publication. This information originates from the reference sections of the citing publications. No additional information source is used. To create the dataset, we start with a corpus of 176,856 papers from PLOS ONE published between 2006 and 2017. While we are interested in citation contexts of highly cited papers we selected all references which are cited in more than 100 PLOS ONE articles. To be able to get additional metadata and keep the problem of deduplication away, we choose only references with PubMed ids in the reference part of the citing publications. An example of a citation context with related metadata is shown in Table 1. In total, the number of references cited in more than 100 publications is 666. 127 publications are discarded because of missing PubMed id. In the next step, we filter all citation contexts which do not reference one of the top-666 publications. Because not every publication in our corpus is referencing one of these publications, the number of citing papers used in our study shrinks down to 62,127.

Corpus statistics

The number of relevant citation contexts for our analysis is 173,630. This number reflects the fact, that only in 0.5 percent of the citation contexts (total: 31,746,769) at least one top reference is cited. These top-referenced publications are published between 1951 and 2015. Only 69 of them are published before 2010. We have to keep in mind that just for cited articles published after 2007 it is possible to examine statistics for short citation intervals. The distribution of the number of citation contexts per top-666 follows a power-law-like shape. The most cited reference is mentioned in 3,363 citation contexts. This reference is a method paper by Livak and Schmittgen[3] titled "Analysis of relative gene expression data using real-time quantitative PCR and the 2(-Delta Delta C(T)) method". The lowest number of citation contexts is 75, where the median reference is mentioned in 184 contexts.

Results

Distribution over sections

The first question we want to answer with the data from our corpus for the top-666 references is: In which section are the top-666 cited (RQ 1)? Small (2018) used the share of citation contexts located in the method section of a citing publication to predict what type of reference it is. The usefulness of this feature to predict the type of the referenced publication provides a hint, that their usage in a specific section could distinguish highly cited references. Figure 1 shows for each of our top-666 references on the x-axis the proportion of sections in which the citation contexts were found. For more than half of our references the most used section for citing is the method section. But on the other hand, there is a larger group of references which are mainly used in introduction and discussion. We tried to correlate the section usage with the mean citation interval of the top-666. This did not show a significant result. In general, this means, that the section usage of a reference is not dependent on the age of a reference while citing.

Sections of citation contexts over time

To be able to delineate the influence of age of referenced literature and the type of the section in the citing papers we measure the citation interval (RQ 2). The citation interval is the time distance between the publication date of the citing paper and the publication date of the reference paper. We accumulate all citation contexts in groups for each possible citation interval to the corresponding reference. This grouping results in a minimum of zero years to a maximum of 65 years. Of course, the amount of citation contexts in each group varies. Eighty percent of the citation intervals are between 5 to 20 years. For citation intervals larger than 25 years, we have not much account on absolute numbers of citation contexts as well as number of different referenced objects. For each group, we calculated the share of sections and visualized the results in Figure 2.

The result of this analysis is that a reference with a high citation interval, i.e. an older publication at the time of citing, is likely to be used in a method part. The second result is that there is a change for the most frequently used section based on the citation interval at the beginning of a reference lifetime (0-3 years). In the first two years, a top-cited publication is more likely to be used in the introduction part, later it is more often used in the method part. This usage is a hint that the function of the citation is changing over time and needs further examination in future work.

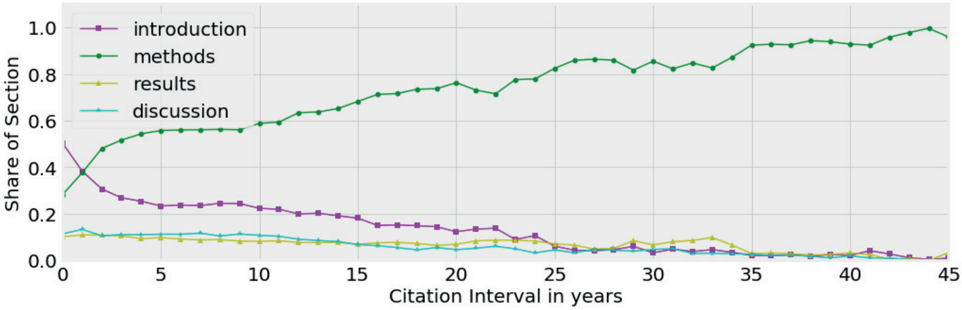

Figure 2. The proportion of IMRaD sections over time.

Number of co-citations on citation context level

The third introspection (RQ 3) of the usage of highly cited references concerns their co-citation on the citation context level. For each relevant context based on citing a top-666 reference we count the number of all references. This approach is defined by Liu & Chen (2012) as sentence-level co-citation. The fact that a publication is referenced alone in one citation context could be a sign that the reference stands on its own and there seems to be no need of citing similar publications. The larger the citation interval is, the higher could be the probability, that there is a low number of co-cited publications in the same sentence.

To investigate the number of co-citations depending on the citation interval, we binned all citation contexts for each citation interval (0-40 years) separately. For each year we have calculated the mean value from the number of quotations per citation context. The mean value is between 1 and 2. Figure 3 (a) shows that the mean value is declining. We calculated the coefficients of a linear regression describing this correlation which is *-0.54* and stated to describe a significant relation. But probably we have to include the knowledge that the higher the citation interval, the greater the probability that the citation context is in a method part of a paper. This fact raises the question whether this phenomenon is also able to describe the declared co-citation time effect.

Here we can come up with a derived research question: Is the high proportion of "method"-citation contexts within longer citation intervals explaining the change of co-citation mean? To answer this question, we divide the citation context into four groups based on location in one of the sections *Introduction, Methods, Results, and Discussion*. After this grouping, we applied the same procedure as for the first calculation. Figure 3 (b) reflects the mean co-citation number in the context given a citation interval for different sections. For all the curves we figured out that there are no significant relations between citation interval and the number of co-citations. We combine the results of this non-significance with the knowledge that the proportion of the citation context of the method increases due to the length of the citation interval (Figure 2). Then, the fact that the mean number of co-citations in the method-contexts is the lowest (Figure 3 (b)) explains the decreasing curve of Figure 3 (a).

Future Work

Future studies aim to replicate results by concerning a larger data corpus, for example by considering the whole PubMed corpus. Also, future research should consider the potential effects of various citation intervals more carefully. For example, analysis of word usage (e.g., adjective, verb, and noun) in citation contexts of highly cited papers and changes over time might be addressed. Besides, the categorization of the cited works into different types or disciplines by their citation contexts could be an essential field for future research.

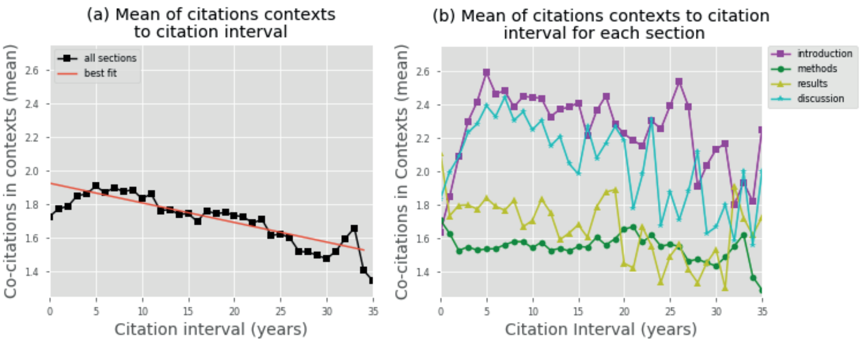

Figure 3. The curves describe the decrease of the mean number of co-citation in contexts for longer citation intervals. (a) Describes the overall decline incl. the best-fit line. (b) Reflects the means for each section individually.

Abstract

Government funding and international collaboration play significant roles in science development. Both may play roles in publication citation impact. The current study focused on funded international collaboration in six countries (i.e., China, Brazil, South Africa, Germany, The Netherlands and US). Different countries vary in arrangement of government funding sources in support of competitive research projects. China and Brazil are centralized to a unique agency (i.e., NSFC and CNPq), whereas the rest four countries are relatively decentralized. The six focal agencies of the current study (i.e., NSFC, NSF, DFG, NWO, NRF and CNPq) are more efficient than non-focal agencies in general in raising citation impact, with NSF of US performs best. Not all countries get benefit from international collaboration in terms of raising citation impact of publications: developing countries (i.e., China and Brazil in current study) benefit more than developed countries. Collaborating with developed countries especially the US can be a first option for choosing foreign partners. With regard to interaction between funding and international collaboration, DFG performs best in raising citation impact of international collaboration.

Introduction

Government funding plays a significant role in the development of science, and have attracted extensive interests of academic community. Positive effects of government funding in raising citation impact of publications (e.g., Yan, Wu, & Song, 2018) and breakthrough inventions (Corredoira, Goldfarb, & Shi, 2018) have been found. Variations in terms of funding efficiency may exist between different funding systems. Among many factors, national research evaluation systems (Sandström & Van Besselaar, 2016), academic freedom, and university stratification play significant roles in affecting funding efficiency (Sandström & Van den Besselaar, 2018). In current era that scientific discovery increasingly rely on wide-spread collaboration (Bozeman & Corley, 2004; Choi, Yang, & Park, 2015; Cimini, Zaccaria, & Gabrielli, 2016) including international collaboration (Frame & Carpenter, 1979; Wagner, Park, & Leydesdorff, 2015). Studies on international collaborative research have kept expanding so rapidly that some even wonder it as an emerging field (Chen, Zhang, & Fu, 2018; D'Ippolito & Rüling, 2019). In addition to analysing the roles of international collaboration in publication productivity and citation impact (Bozeman, Fay, & Slade, 2013; Lee & Bozeman, 2005; Van Raan, 1998), network position of specific countries (Adams, 2012; Guan, Yan, & Zhang, 2017; Todeva & Knoke, 2005; Wang, Wang, & Philipsen, 2017; Zhao & Guan, 2011), as well as collaboration patterns (Leydesdorff & Wagner, 2008; Todeva & Knoke, 2005) are also important topics. The effect of international collaboration in raising citation impact of publications of different countries vary significantly and is very much dependant on collaborating partners (Bote, Olmeda-Gómez, & de Moya-Anegón, 2013; Lancho-Barrantes, Guerrero-Bote, & de Moya-Anegón, 2013; Sud & Thelwall, 2016). Collaborating with the US especially with US researchers as corresponding authors would benefit most (Bote et al., 2013;

De Moya-Anegon, Guerrero-Bote, Lopez-Illescas, & Moed, 2018; Moya-Anegón, Guerrero-Bote, Bornmann, & Moed, 2013).

The above studies imply that both funding and international collaboration play significant roles in scientific research, which leads to perspectives combining the two factors together. One typical perspective is on the role of funding in facilitating international collaboration, and with no exception, positive effect has been confirmed (Cimini et al., 2016; Clark & Llorens, 2012; Liu, Liang, Tuuli, & Chan, 2018; Ubfal & Maffioli, 2011). Another popular perspective is to investigate if international collaboration facilitates access to funding supports (Zhou & Tian, 2014). Some studies explore the effect of funding and international collaboration separately on citation impact without investigating if mutual effect exists between the two factors together (Leydesdorff, Wagner, & Bornmann, 2019; Zhou, Zhong, & Yu, 2013). International collaboration plays positive role in raising citation impact but the effect of government funding tends to be a small adverse (Leydesdorff et al., 2019).

In fact, funding and international collaboration may interact with each other, and thus affect citation impact comprehensively. The current study will contribute in this regard. Considering that the effect of the two factors (i.e., funding support and international collaboration) on citation impact may also be dependent on other factors such as collaboration size, funding sources, research fields, and so on, the current study will take most of the possible factors into account by focusing on publications acknowledging government funding supports of six different countries, so as to clarify the following questions: (1) What is the contribution of funded research to science? Does country variation exist? (2) Is there difference in terms of citation impact between publications acknowledging support of national funding agencies of different countries? (3) What is the role of international collaboration in different countries? Is the effect of first and corresponding authorship different? Does effect of collaboration with developed countries the same as that with developing countries? (4) How do funding and international collaboration interact with each other? Upon answering the four questions, discussion will be carried out.

Data and methods

Bibliometric data in 2009-2016 are extracted from the CWTS-licensed version of the Web of Science (WoS) database of Clarivate. Six countries, namely, China, Brazil, South Africa, Germany, The Netherlands, and the US are included to illustrate the situations in both developing and developed countries. The targeted funding agencies (will be called *focal agencies* latter) supporting basic research of the six countries are the National Natural Science Foundation of China (NSFC), National Council for Scientific and Technological Development of Brazil (CNPq), National Research Foundation of South Africa (NRF), German Research Foundation (DFG), The Netherlands Organization for Scientific Research (NWO), and the US National Science Foundation (NSF). Funded publications are harvested from CWTS funding organization database originated from the WoS index fields FO and FT.

Field classification is based on CWTS' 35 subject categories. Because not all scientific fields are supported by the focal agencies of the current study, we only cover subject categories that are main supporting areas of the six funding agencies. Thus, 22 subject categories[1] remained. Since the current study focuses on journal publications, only those with journal papers as main form of research outcome will be covered. Although highly productive in journal publications, the area *Clinical Medicine* is not covered because it is not the major area supported by the National Science Foundation (NSF). In the end, six subject categories including *Basic Life Sciences, Biological Sciences*, *Chemistry & Chemical Engineering*, *Environmental Sciences & Technology*, *Mathematics* as well as *Physics & Materials Science* remain.

Two sets of indicators measuring publication productivity and citation impact are used. For productivity measurement, we apply percentage of funded publications and top-1% highly cited publications. The former measures the extent of funded research, and the latter measures high-quality research. The *Mean Normalized Citation Scores* (MNCS) of CWTS is used to measure average citation impact of a publication set under variable citation window.

International collaboration is defined as two or more countries appear in author addresses of a publication. Single-author publications are considered non-international collaboration even if different country affiliations appear. Publications with two authors in which both share the same country and one of them has a second country affiliation would be treated as international collaboration. In co-authored publications, the roles of different authors vary with that of first and corresponding authors most significant. Investigating country affiliations of first or corresponding authors may provide deeper insights on the role of a country in international collaboration. The positive roles of US corresponding authors have been found in different studies (Bote et al., 2013; De Moya-Anegon et al., 2018; Lancho-Barrantes et al., 2013). The current study will explore both first- and corresponding-authored collaboration of a target country. Because the effect of collaboration with scientific leading and following countries may differ, we classify countries into two sets - Group 7 countries (i.e., Canada, France, Germany, Italy, Japan, the United Kingdom, and the United States) and non-G7 countries. Collaboration with US will be analyzed specially because of its absolute leading position in science.

To analyze the effect of different factors on citation impact, publications are classified into different types as illustrated in Table 1.

Table 1. Publication classification.

Publication set	*Definition*
All publication	All publications regardless of funded or not.
PFA	Publications acknowledging any types of funding support.
PFAs*	Publications acknowledging funding support of a focal agency (i.e., NSFC, NSF, DFG, NWO, CNPq, NRF).
PFA without PFAs	Publications not including financial support of the focal agencies.
PnotFA	Publications without funding acknowledgement.
PFAs and IntNatl	Internationally collaborated publications acknowledging funding support of a focal agency.
(PFA without PFAs) and IntNatl	Internationally collaborated publications with funding not including the focal agencies.
First country	First-author publications of a target country in international collaboration.
Reprint country	Corresponding-author publications of a target country in international collaboration.
G7 countries	Canada, France, Germany, Italy, Japan, the UK, and the US

* There may exist publications claiming to be funded by a focal agency but no authors from that country, which may interfere with a country-based result. To avoid such situation happening, we further define a publication set funded by a focal agency in the following way: A publication acknowledging funding support of a focal agency should have author(s) from the country of the focal agency. For example, a publication acknowledging NSF grant should have author(s) from the USA.

Results

Both descriptive and regression results will be illustrated. Ordinary Least Square (OLS) regression with robust standard errors is used to measure effect of funding and/or international collaboration on citation impact of different types of publication sets.

Descriptive analysis

Funding supports play important roles in national publication production. Around 67% of publications of the six countries have acknowledged grant support. With over 83% of funded publications, China is most prominent. Situations in the rest five countries are similar (62% ~ 67%). In terms of percentage of publications acknowledging grant of the focal agencies in the total national funded publications (i.e., % (PFAs/PFA)), that of NSFC is the highest (69%). In other words, about 69% of China's funded publications are supported by NSFC. The role of CNPq is similar, it contributes about 65% of Brazil's funded publications. The NSF's percentage contribution to US funded publications is the least (18%), whereas that of DFG, NRF and NWO are respectively 36%, 27% and 23% (Figure 1a).

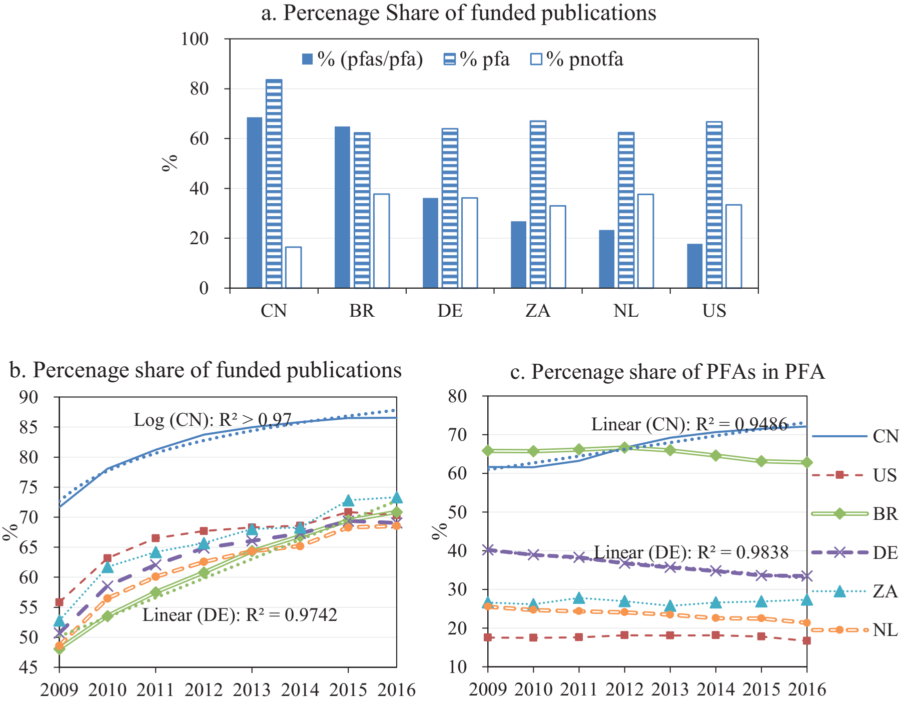

Figure 1. Output and annual trend in 2009-2016

The percentage share of funded publications in national total has kept growing, although each country has its own trend. China has the highest percentage and grows logarithmically. The growth trend of Brazil has kept strong. The rest four countries share similar trends with growth styles changed in 2014 and converged at around 68% in 2016 (Figure 1b). With respect to percentage of publications funded by the focal agencies (PFAs in PFA), that of NSFC has kept growing. There is no significant change for that of NRF. Percentage decline is also seen for the rest four agencies, especially DFG and NWO (Figure 1c).

Citation impact of all publication sets measured by MNCS is, however, a different landscape. The Netherlands performs best in the three types of publications (i.e., PFA, PFAs, and PnotFA), followed by the US and Germany. Publications with funding support perform, in general, better than unfunded publications. With significantly higher citation impact than all-funded publications of US, NSF-supported publications perform best, followed by those funded by NWO and NSFC. In contrast to the US situation, citation impacts of all funded publications of

Germany, South Africa and Brazil are higher than those funded by the focal agencies of the corresponding countries (i.e., DFG, NRF, and CNPq). NSFC funding is critical to Chinese publications in raising citation impact. NSFC-funded publications have higher citation impact than those funded by NRF, although unfunded publications of China have lower citation impact than unfunded publications of South Africa (Figure 2a). As expected, similar situation happens in producing highly-cited publications. The Netherlands performs best, followed by the US and Germany.

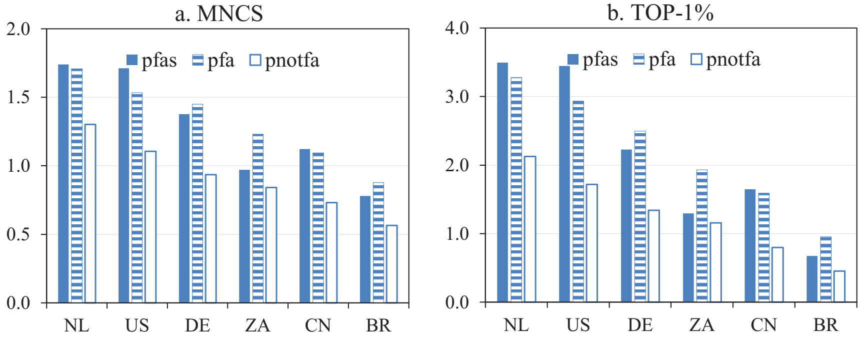

Figure 2. MNCS and percentage of top-1% highly cited publications (2009-2016).

Regression analysis

The effect of different independent variables on citation impact measured by *NCS* (i.e., the dependent variable) is obtained by applying OLS regression (Table 2). The independent variables include funding types (i.e., *PnotFA, PFA without PFAs*, *PFAs*), international collaboration (i.e., *IntNatl*), internationally collaborated publications acknowledging funding support not from the focal agencies (i.e., *PFA without PFAs* and *IntNatl*), internationally collaborated publications acknowledging support of the focal agencies (i.e., *PFAs and IntNatl*), first-author publications, reprint (or corresponding) publications, as well as publications collaborated with US, G6 or non-G7 countries. Interaction between funding support and international collaboration is also included to investigate synergy between funding support and international collaboration. Other factors including publication year, number of references, number of authors, number of institutions, number of countries, publication types (i.e., review, article), as well as scientific fields may also affect citation impact, and thus are set as controlled variables.

Funding support, regardless of focal- or non-focal-agency sources, has positive effect on citation impact of publications, although such contribution varies among countries and depends on the variables. Except DFG and NRF, the effects of NSFC, NSF, NWO and CNPq are higher than non-focal-agency funding of the same country. Citation impact of Chinese publications with non-NSFC funding support is 7.3% higher, whereas those with NSFC funding is 10.1% higher than those with no funding support ($e^{0.071}$ and $e^{0.096}$). For US publications, non-NSF funding support may raise citation impact by 6.9% whereas NSF support has higher effect of 10.8% ($e^{0.067}$ and $e^{0.103}$). The Dutch NWO raised citation impact by 10.4%, which is higher than 7.1% of those with non-NWO funding ($e^{0.069}$ and $e^{0.099}$). Similar situation applies to Brazilian CNPq and non-CNPq funding. The opposite is true in Germany: citation-impact-raising effect (by 9.4%) of non-DFG funding is higher than DFG funding (by 4.8%) ($e^{0.090}$ and $e^{0.047}$). The situation in South Africa is most unique – there is no significant change of citation impact of publications funded by NRF whereas non-NRF funding can raise citation impact by 1.2%.

The effect of international collaboration varies between countries. With 12.9% increase of citation impact by collaborating with foreign partners, China benefits most among the six countries. Brazil is also a beneficiary with 7.9% increase of citation impact. On the contrary, the rest four countries including the US, The Netherlands, South Africa and Germany have citation impact been reduced respectively by 8.1%, 6.7%, 4.6% and 4.0% in collaborating with other countries. When the interaction between funding and international collaboration is considered, the situation is a little bit complex. The effect of non-focal-agency (*PFA without PFAs*) support on raising citation impact of internationally collaborated publications is lower than that of non-internationally collaborated publications of countries like China, Germany and The Netherlands, but slightly higher than that of non-internationally collaborated publications of a country like the US and South Africa. There is no significant difference in internationally collaborated publications of Brazil whether with or without non-focal-agency support. The effect of the focal agencies on raising citation impact of internationally collaborated publications is lower than that on publications of non-international collaboration in China, Brazil, and Netherlands, and is higher in Germany, but no significant difference in US and South Africa. In general, funding support, regardless with or without the focal agencies (i.e., NSFC or NWO) of China and The Netherlands, may be less effective in raising citation impact of internationally collaborated publications than in raising citation impact of non-internationally collaborated publications. In contrast to the rest five focal agencies (i.e., NSFC, NSF, CNPq, NRF, NWO), German DFG performs better in raising citation impact of internationally collaborated publications than that of publications of non-international collaboration (Table 2).

[a] According to F test, there are significant differences between coefficients of *Pfa without Pfas* and *Pfas* in models 1-4 and 6.

Different roles and partners with different scientific positions may also affect citation impact. When developed countries (i.e., US, Germany, and The Netherlands) act as first authors, citation impact would be higher than non-first authorship of these countries. On the contrary, when developing countries (i.e., China, Brazil and South Africa) act as first authors, citation impact of publications would be lower than those of non-first authorship of the three countries. When corresponding authorship is considered, similar results happen to China and Brazil: International collaboration with Chinese or Brazilian researchers acting as corresponding authors, citation impact would be lower than those of non-corresponding authorship of the two countries. The positive role of US happens again when corresponding authorship is concerned. The effect of corresponding authorship of the rest countries (i.e., Germany, Netherlands, and South Africa) is insignificant. The outstanding role of US in raising citation impact of internationally collaborated publications is further confirmed by the standardized coefficients of OLS regression. Collaborating with G7 countries excluding the US is also a way of raising citation impact, although such effect is less than that collaborating with US. Non-G7 countries may also help raising citation impact of the six target countries except Germany, but with the least effect among the three types of partner countries (i.e., US, G6, and non-G7). The situation of China is exceptional: collaborating with non-G7 countries may have higher citation impact than collaborating with G6 countries (Table 3).

Conclusions and discussion

With absolute high percentage of publications supported by the focal agencies, China and Brazil have more centralized government resources supporting basic research than the rest four countries. The NSFC of China supports basic research in almost all areas, while in the US, the responsibility for supporting basic research is spread across the National Science Foundation (NSF), National Institute of Health (NIH), and Department of Energy (DOE). The percentage share of funded publications in all publications of a country has kept growing, and each country has its own way of growth. China has the highest percentage of funded publications, and the percentage of NSFC in the funded total has kept growing, which is in stark contrast to the focal agencies in the other five countries, especially DFG and NWO with a decreasing share. In other words, Chinese researchers rely heavily on NSFC funding whereas US, Germany, Dutch and South African scholars have more options in seeking national funding sources.

With regard to citation impact and top-1% highly cited publications, developed countries (i.e., The Netherlands, US and Germany) perform better than developing countries (i.e., South Africa, China and Brazil), and Netherlands performs best. Funding supports are important in raising citation impact, although variations exist among countries. In supporting high-quality research in terms of citation impact, some focal agencies like NSF are more efficient than non-NSF funding support, some (i.e., NWO and NSFC) do not make much difference from non-focal agencies, and some (i.e., DFG, NRF, and CNPq) even are less efficient.

The positive effect of funding support in raising citation impact of publications is further confirmed in OLS regression analysis. Citation-raising effect of most of the focal agencies (i.e., NSFC, NSF, NWO and CNPq) are usually higher than that of non-focal agencies. Nonetheless, it is not true in German and South African situation. The situation in South Africa is most unique – there is no significant change of citation impact of publications funded by NRF whereas non-NRF funding can raise citation impact.

Not all countries get benefit from international collaboration in terms of raising citation impact of a nation's publications. In most cases, developing countries benefit more than developed countries. Collaborating with developed countries especially with the US can be a first option in choosing international partners. Although citation impact might be lowered in collaborating with developing countries, such collaboration should still be encouraged for developed countries, because it may complement shortage of human resources and help young scholars from developing countries grow up.

When interaction of funding support and international collaboration is concerned, the situation is very much dependent on countries and funding sources. The citation-raising effect of non-focal-agency funding on international collaboration is slightly lower than on non-international collaboration of China, Germany and The Netherlands, but slightly higher on international collaboration of US and South Africa. To Brazilian publications, effect of non-focal-agency support in raising citation impact of publications with or without international collaboration does not show significant difference. The impact-raising effect of the focal agencies in publications with international collaboration over non-international collaboration also varies – some (i.e., NSFC or NWO) with less efficiency, some (i.e., NSF, NRF) with insignificant difference; the German DFG is the only one that is more efficient. An important reason, among others that may lead to the different effect of the six focal agencies on citation impact, can be evaluation principles for research projects. The DFG practice can be an excellent example for other agencies supporting research in basic science.

Abstract

Adequately disambiguating author names in bibliometric databases is a precondition for conducting reliable analyses at the author level. In the case of bibliometric studies that include many researchers, it is not possible to disambiguate each single researcher manually. Several approaches have been proposed for author name disambiguation but there has not yet been a comparison of them under controlled conditions. In this study, we compare a set of unsupervised disambiguation approaches. Unsupervised approaches specify a model to assess the similarity of author mentions a priori instead of training a model with labelled data. In order to evaluate the approaches, we applied them to a set of author mentions annotated with a ResearcherID, this being an author identifier maintained by the researchers themselves. Apart from comparing the overall performance, we take a more detailed look at the role of the parametrization of the approaches and analyse the dependence of the results on the complexity of the disambiguation task. It could be shown that all of the evaluated approaches produce better results than those that can be obtained by using only author names. In the context of this study, the approach proposed by Caron and van Eck (2014) produced the best results.

Introduction

Bibliometric analyses at an individual level depend on the adequate identification of the authors' oeuvres. At best, all of an author's papers should be considered without fail, while other papers should not be falsely assigned to that author. Getting as close as possible to this ideal situation is especially important since poorly disambiguated data may distort the results of analyses at an author level (Kim and Diesner 2016; Kim 2019). Some identifiers that uniquely represent authors are available in bibliometric databases. These, however, are maintained by the researchers themselves (e.g. ResearcherID, ORCID) – implying a low coverage and the possibility of deliberate false assignments – or are based on an undisclosed automatic assignment (e.g. Scopus Author ID) – which does not allow an assessment of the quality of the algorithm (the algorithm is not publicly available). Automatic approaches that try to solve the task of disambiguating author names have thus been proposed in bibliometrics. This task presents a non-trivial challenge since different authors may have the same name (homonyms) and one author may publish under different names (synonyms).

Table 1. Examples for homonyms and synonyms in bibliometric databases

Publication title	Author name	Author ID
Social theory and social structure	R. Merton	1
The Matthew effect in science	Robert Merton	1
Allocating Shareholder Capital to Pension Plans	Robert Merton	2

Table 1 shows the titles, the author names and an author identifier for three publications, including both homonyms and synonyms. The author names of the first two publications are synonyms since they refer to the same person but differ in terms of the name. The author names of the last two publications are an example of homonyms since they refer to different persons but share the same name.

In this study, we compare four unsupervised disambiguation approaches. In order to evaluate the approaches, we applied them to a set of author mentions annotated with a ResearcherID, this being an author identifier maintained by the researchers themselves. Apart from comparing the overall performance, we take a more detailed look at the role of the parametrization of the approaches and analyse the dependence of the results on the complexity of the disambiguation task.

Related work

In order to find sets of publications corresponding to real-world authors, approaches for disambiguating author names try to assess the similarity between author mentions by exploiting metadata such as co-authors, subject category, journal, etc. In order to reduce runtime complexity and exclude a high number of obvious false links between author mentions, most approaches reduce the search space by blocking the data in a first step (On et al. 2005). The idea is to generate disjunctive blocks so that author mentions in different blocks are very likely to refer to different identities, and therefore the comparisons can be limited to pairs of author mentions within the same block (Newcombe 1967; Levin et al. 2012). A widely used blocking strategy for disambiguating author names in bibliometric databases is to group together all author mentions with an identical canonical representation of the author name, consisting of the first name initial and the surname (On et al. 2005).

The algorithms to disambiguate author names that have been proposed up to now differ in several respects (Ferreira, Gonçalves, and Laender 2012). One way to distinguish between different approaches is to classify them as either unsupervised or supervised (Smalheiser and Torvik 2009). Supervised approaches try to train the parameters of a specified model with the help of certain training data (e.g., Torvik and Smalheiser 2009; Ferreira et al. 2010; Levin et al. 2012; Ferreira et al. 2014). The training data contains explicit information as to which author mentions belong to the same identity and which do not. The model trained on the basis of this data is then used to detect relevant patterns in the rest of the data. Unsupervised approaches, on the other hand, try to assess the similarity of author mentions by explicitly specifying a similarity function based on the author mentions' characteristics. We will focus on unsupervised approaches in the following. Supervised approaches entail several problems, especially the challenge of providing adequate, reliable and representative training data (Smalheiser and Torvik 2009).

The unsupervised approaches for disambiguating author names that have been proposed so far vary in several ways. First, every approach specifies a set of attributes and how these are combined to provide a similarity measure between author mentions. In order to determine which similarities are high enough to consider two author mentions or two groups of author mentions as referring to the same author, some form of threshold for the similarity measure is necessary. This threshold can be determined globally for all pairs of author mentions being compared, or it can vary depending on the number of author mentions within a block that refers to a single name representation. Block size dependent thresholds try to reduce the problem of an increasing number of false links for a higher number of comparisons between author mentions, i.e. for larger name blocks (Caron and van Eck 2014; Backes 2018).

Another way in which the approaches differ is the clustering strategy that is applied, i.e. how similar author mentions are grouped together. All clustering strategies used so far in the context of author name disambiguation can be regarded as agglomerative clustering algorithms (Ferreira, Gonçalves, and Laender 2012), especially in the form of single-link or average-link clustering. More specifically, single-link approaches define the similarity of two clusters of author mentions as the maximum similarity of all pairs of author mentions belonging to the different clusters. The idea behind this technique is that each of an author's publications is similar to at least one of his or her other publications. In average-link approaches, on the other hand, the two clusters with the highest overall cohesion are merged in each step, i.e. all objects in the clusters are considered (in contrast to just one from each cluster in single-link approaches). This rests on the assumption that an author's publications form a cohesive entity. As a consequence, it is easier to distinguish between two authors with slightly different oeuvres compared to single-link approaches, but heterogeneous oeuvres by a single author are more likely to be split.

Previous author name disambiguation approaches have usually been evaluated in terms of their quality. This evaluation is always based on measuring how pure the detected clusters are with respect to real-world authors (precision) and how well the author mentions of real-world authors are merged in the detected clusters (recall). However, different metrics have been applied when assessing these properties. Furthermore, different datasets have been used to evaluate author name disambiguation approaches (Kim 2018). It is therefore difficult to compare different approaches based on their previous evaluations.

Approaches compared

We focused on unsupervised disambiguation approaches in our analyses (see above). Since these approaches require no training data to be provided a priori, they are more convenient for use with real-world applications. Furthermore, narrowing the set of approaches down to unsupervised ones facilitates their comparison, whereas more aspects have to be considered if they are compared with supervised approaches (e.g., the quality of the training data, which type of supervised model is chosen), making this kind of a comparison more incomprehensible. We chose four approaches in addition to a naïve approach, which only considers the canonical representation of author names. These were selected to cover a wide variety of features that characterize unsupervised approaches for disambiguating author names. We applied the approaches to data from the Web of Science (WoS, Clarivate Analytics) that had already been pre-processed according to a blocking strategy, as described above. More precisely, all author mentions that share the author name representation specified by surname and first initial of the first name have been assigned to the same block. Therefore, all author mentions referring to one real-world author should be in one of these blocks, but there may be several authors represented by one name block. However, there were already some splitting errors in the blocking step (e.g. spelling errors, errors due to name changes).

Implementation of the four selected disambiguation approaches

(1) Cota, Gonçalves and Laender (2007) proposed a two-step approach that considers the names of co-authors, publication titles and journal titles. In a first step, all pairs of author mentions that share a co-author name are linked. The linked author mentions are then clustered by finding connected components with regard to this matching. The second step iteratively merges these clusters if they are sufficiently similar with respect to their publication titles or journal titles. The similarity of two clusters (one for publication titles, one for journal titles) is defined as the cosine similarity of the two TF-IDFs (term frequency-inverse document frequency) for the clusters' publication titles (or journal titles). Two clusters are merged if one of their similarities (either with regard to publication titles or to journal titles) exceeds a predefined threshold. This process continues until there are no more sufficiently similar clusters to merge, or until all author mentions are merged into one cluster.

(2) Schulz et al. (2014) proposed a three-step approach based on the following metric for the similarity s_{ij} between two author mentions i and j:

$$s_{ij} = \alpha_A \left(\frac{|A_i \cap A_j|}{\min(|A_i|,|A_j|)}\right) + \alpha_S\left(|p_i \cap R_j| + |p_j \cap R_i|\right) +$$
$$\alpha_R\left(|R_i \cap R_j|\right) + \alpha_C \left(\frac{|C_i \cap C_j|}{\min(|C_i|,|C_j|)}\right) \quad \text{(I)}$$

Here, A_i denotes the co-author list of paper i, R_i its reference list and C_i its set of citing papers. The first step links all pairs of author mentions with a similarity (determined by formula (I)) exceeding a threshold β_1 and a set of clusters is determined by finding the corresponding connected components. In the second step, these clusters are merged in a very similar way. In order to determine the similarity $S_{\gamma\kappa}$ of two clusters γ and κ, the similarities between author mentions within these clusters are combined by means of the following formula:

$$S_{\gamma\kappa} = \sum_{i\in\gamma j\in\kappa} \frac{s_{ij}\Theta(s_{ij})}{|\gamma||\kappa|}, \; \Theta(s_{ij}) = \begin{cases} 1 \; if \; s_{ij} > \beta_2 \\ 0 \; if \; s_{ij} \leq \beta_2 \end{cases} \quad \text{(II)}$$

Here, |γ| denotes the number of author mentions in cluster γ (similarly for cluster κ). As the formula shows, only those similarities between author mentions that exceed a threshold β_2 are considered when calculating the similarity between two clusters. As in the first step, this cluster similarity is used to link clusters if they exceed another threshold β_3 in order to find the corresponding connected components. The third step of this approach finally adds single author mentions that have not been merged to a cluster in either of the first two steps, provided its similarity with one of the cluster's author mentions exceeds a threshold β_4.

(3) Caron and van Eck (2014) proposed measuring the similarity between two author mentions based on a set of rules that rely on several paper-level and author-level characteristics. More precisely, a score is specified for each rule, and all of the scores for matching rules are added up to an overall similarity score for the two author mentions (see Table 2). If two author mentions are sufficiently similar with regard to this similarity score, they are linked and the corresponding connected components are considered oeuvres of real-world authors. The threshold for determining whether two author mentions are sufficiently similar depends on the size of the corresponding name block. The idea behind this approach is to take into account the higher risk of false links in larger blocks. Higher thresholds are therefore used for larger blocks to reduce the risk of incorrectly linked author mentions.

Table 2. Rules for rule-based scoring proposed by Caron and van Eck (2014)

Field	Criterion	Score
Email	exact match	100
All initials, more than one	exactly two matching initials	5
	more than two matching initials	10
	conflicting initials	-10
First name	matching general name	3
	matching non-general name	6
Address (linked to author)	matching country and city	4
Co-authors	one shared co-author	4
	two shared co-authors	7
	more than two shared co-authors	10
Grant number	at least one shared grant number	10
Address (linked to publication, but not linked to author)	matching country and city	2
Subject category	matching subject category	3

Journal	matching journal	6
Self-citation	at least one publication citing the other	10
Bibliographic coupling	exactly one shared cited reference	2
	exactly two shared cited references	4
	exactly three shared cited references	6
	exactly four shared cited references	8
	more than four shared cited references	10
Co-citation	exactly one shared citing reference	2
	exactly two shared citing references	3
	exactly three shared citing references	4
	exactly four shared citing references	5
	more than four shared citing references	6

(4) Backes (2018) proposed an approach that starts by considering each author mention as one cluster. An agglomerative clustering algorithm is then employed that iteratively merges clusters if they are sufficiently similar, i.e. two clusters are connected if their similarity exceeds a quality limit l. The similarity metric indicating how similar two clusters are takes into account the specificity of the author mentions' metadata. For example, if two author mentions share a very rare subject category this might be a stronger indicator of the author mentions for the same author compared to a very common subject category. This strategy is applied to compute a similarity score for each characteristic under consideration. When using this approach in our study, we considered the following characteristics: titles, abstracts, affiliations, subject categories, keywords, co-author names, author names of cited references, and email addresses. Backes (2018) proposed several variants to combine these scores into a final similarity score of two clusters. In the variant implemented in this study, the scores are combined in the form of a linear combination with equal weights for all characteristics' scores. Each iteration of the clustering process merges all pairs of current clusters whose similarity exceeds l. The quality limit l is designed to have a linear dependence on the block size $|author\ mentions|$, whereby the parameter λ specifies this relationship (see formula (III)).

$$l = \lambda \cdot |author\ mentions| \qquad \text{(III)}$$

Parameter specification

Some form of threshold (or a set of thresholds) has to be specified for each of the four approaches. Since such thresholds have not been proposed for all approaches by the authors, and some of the proposed thresholds produce poor results for our dataset, we fitted them with regard to our data. This allows a better comparability since the thresholds are matched to the particular datasets they are applied to. Our procedures for specifying the thresholds maximize the evaluation metrics $F1_{pair}$ and $F1_{best}$ (see below).

We specified such a procedure for each of the approaches that allowed an efficient consideration of a wide range of thresholds. A set of thresholds uniformly distributed over the complete parameter space was chosen as candidate set for the approach of Cota, Gonçalves and Laender (2007). We also specified the thresholds for the approach of Schulz et al. (2014) by evaluating a candidate set of parameters; in this case, the candidate set of thresholds was chosen on the basis of the parameters proposed in the original paper. The parametrization of this approach was further optimized by fitting β_1, β_2 and β_3 independently from β_4. β_4 was subsequently chosen based only on the best combination of the other thresholds, which substantially reduces the search space. We believe this to be an adequate procedure for finding the thresholds since the last step of this disambiguation approach (which is based on β_4) has only a minor influence on the final result. For the approach proposed by Caron and van Eck (2014) we initially had to define the block size classes that divide the blocks into several classes with regard to the number of author mentions in them. Similar to Caron and van Eck (2014), we defined six block size classes. Our specification of the classes aims at reducing the variance of optimal thresholds within a class.

For the approach of Backes (2018), we had to modify the approach slightly in order to define a feasible procedure for fitting the parameter λ, which determines the quality limit l for a given block. Instead of linking all pairs of clusters whose similarity exceeds a given l in each iteration, we iteratively merged only those pairs of clusters whose similarity equals the maximum similarity of all current pairs of clusters (the clusters are recomputed after each merger). These similarities were taken as estimates for the quality limit that would yield the clustering of the corresponding merger step. This modification may produce results that are different to the original approach, since the order in which the author mentions are merged may change and the similarities between clusters depend on the previous mergers. However, we assume that these changes would produce only minor differences that do not influence any general conclusions on the approach. Our implementation merges the most similar clusters in each iteration, i.e. the most reliable mergers are applied iteratively until the quality limit is reached. Correspondingly, the original approach follows the idea that all cluster similarities exceeding a certain quality limit indicate reliable links between the corresponding clusters.

Data

We collected metadata for a subset of author mentions from the WoS for our analyses. In order to provide a gold standard that represents sets of author mentions corresponding to real-world authors, we only took author mentions with a ResearcherID linked to them in the WoS into account. More specifically, all person records that are marked as authors and that have a ResearcherID linked to at least one paper published in 2015 or later have been considered. It is very likely that this procedure excludes all author mentions with ResearcherIDs referring to non-author entities (e.g. organizations) and takes into account only such ResearcherIDs that have been maintained recently. We applied the same standardization for all name-based metadata as was used to block author mentions, i.e. a canonical name representation is used consisting of first name initial and surname. We only considered name blocks comprising at least five real-world authors. This selection allowed us to focus on rather difficult cases where the author mentions in a block actually have to be disambiguated across several authors. All in all, this data collection procedure results in 1,057,978 author mentions distributed over 2,484 name blocks and 29,244 distinct ResearcherIDs. The largest name block ("y. wang") comprises 7,296 author mentions.

Results

Evaluation metrics

The evaluation of author name disambiguation approaches is generally based on assessing their ability to discriminate between the author mentions of different real-world authors (precision) and their ability to merge the author mentions of one real-world author (recall). Even though these concepts are widely accepted and referenced, different specific evaluation metrics have been used in the past. In the following, we focus on two types of evaluation metrics. First, we calculate the pairwise precision (P_{pair}), pairwise recall (R_{pair}) and pairwise F1 ($F1_{pair}$) (Levin et al. 2012; Caron and van Eck 2014; Backes 2018) for each of the approaches. Whereas the pairwise precision measures how many of the links between author mentions in the detected clusters are correct, the pairwise recall measures how many of the links between author mentions of real-world authors are correctly detected. Pairwise F1 is the harmonic mean of these two metrics. In formulae (IV)-(VI), $pairs_{author}$ denotes the set of pairs of author mentions where both of the author mentions refer to the same author, and $pairs_{cluster}$ denotes the set of pairs of author mentions where both author mentions are assigned in the same cluster by the disambiguation algorithm. Each of the pairwise evaluation metrics can take values between 0 (no true links between author mentions detected) and 1 (all true links between author mentions detected).

$$P_{pair} = \frac{|pairs_{author} \cap pairs_{cluster}|}{|pairs_{cluster}|} \tag{IV}$$

$$R_{pair} = \frac{|pairs_{author} \cap pairs_{cluster}|}{|pairs_{author}|} \tag{V}$$

$$F1_{pair} = \frac{2P_{pair}R_{pair}}{P_{pair}+ R_{pair}} \tag{VI}$$

Second, we calculate metrics to measure how reliably a cluster can be attributed to one specific author (best precision P_{best}) and how well an author can be attributed to one specific cluster (best recall R_{best}).

More specifically, the best precision represents the fraction of author mentions that refer to the most represented author in the corresponding cluster. The most represented author of a cluster is defined as the author with the largest group of author mentions in this cluster. Accordingly, the best recall represents the fraction of author mentions that are assigned to the cluster with the most author mentions of the corresponding author. Similar to the pairwise F1, the best F1 $F1_{best}$ combines best precision and best recall in the form of their harmonic mean. In formulae (VII)-(IX), $author\ mentions_{best\ author}$ denotes the set of author mentions referring to the author most of the corresponding cluster's author mentions refer to, $author\ mentions_{best\ cluster}$ denotes the set of author mentions assigned to the cluster with the most author mentions of the corresponding author and $author\ mentions$ denotes the set of all author mentions. Technically speaking, P_{best}, R_{best} and $F1_{best}$ can also take values between 0 and 1. However, $author\ mentions_{best\ author}$ and $author\ mentions_{best\ cluster}$ will always contain at least one author mention. Actually, these evaluation metrics will thus always be greater than 0.

$$P_{best} = \frac{|author\ mentions_{best\ author}|}{|author\ mentions|} \tag{VII}$$

$$R_{best} = \frac{|author\ mentions_{best\ cluster}|}{|author\ mentions|} \tag{VIII}$$

$$F1_{best} = \frac{2P_{best}R_{best}}{P_{best}+ R_{best}} \tag{IX}$$

Each of these formulae can either be applied to the complete dataset or to a subset of author mentions. For example, the results of one name block can be evaluated by only considering author mentions within this block when computing the evaluation metrics.

Overall results

The results for the approaches described above are summarized in Table 3. The table shows the evaluation metrics described in the previous section for all of the approaches. All of the approaches produce better results than the naïve baseline disambiguation. The approach proposed by Caron and van Eck (2014) performs best among the examined approaches with regard to both $F1_{pair}$ and $F1_{best}$. If one compares the approaches of Schulz et al. (2014) and

Backes (2018), the two evaluation metrics yield different rankings. Whereas the latter approach performs better with regard to $F1_{pair}$, the first performs better with regard to $F1_{best}$. Finally, the approach of Cota, Gonçalves, and Laender (2007) performs only slightly better than the baseline disambiguation. The precision in particular is very low in this case, due mainly to a high number of false links between author mentions in the first step (merging author mentions with shared co-authors).

Table 3. Overall results for all approaches

Approach	P_{pair}	R_{pair}	$F1_{pair}$	P_{best}	R_{best}	$F1_{best}$
Baseline	0.095	1.000	0.173	0.322	1.000	0.487
Cota, Gonçalves, and Laender (2007)	0.111	0.858	0.196	0.442	0.913	0.596
Schulz et al. (2014)	0.453	0.457	0.455	0.799	0.750	0.773
Caron and van Eck (2014)	0.831	0.787	0.808	0.916	0.885	0.900
Backes (2018)	0.674	0.622	0.647	0.761	0.699	0.729

Figure 1 shows the distribution of the disambiguation quality over block sizes (the mean of all blocks of a specific size is plotted). This distribution is shown for the case where the thresholds are specified as described above ("original") and for the case where the optimal thresholds for each single block are used ("flexible"). The results reveal that the disambiguation quality varies strongly across name blocks. The quality generally worsens for large blocks. Therefore, the disambiguation process may produce biases with regard to the frequency of the corresponding name representation. One reason for the disambiguation quality's dependence on the size of the name block is the larger search space to find clusters of author mentions. This increases the search complexity in general, implying a greater potential for false links between author mentions. Some approaches try to reduce this problem by allowing for block size dependent thresholds (see next section). Even though the negative relationship between block size and disambiguation quality can be observed for all approaches, the decline in quality is not equal in all of them. Especially for the approach of Caron and van Eck (2014), the influence of the block size is relatively small.

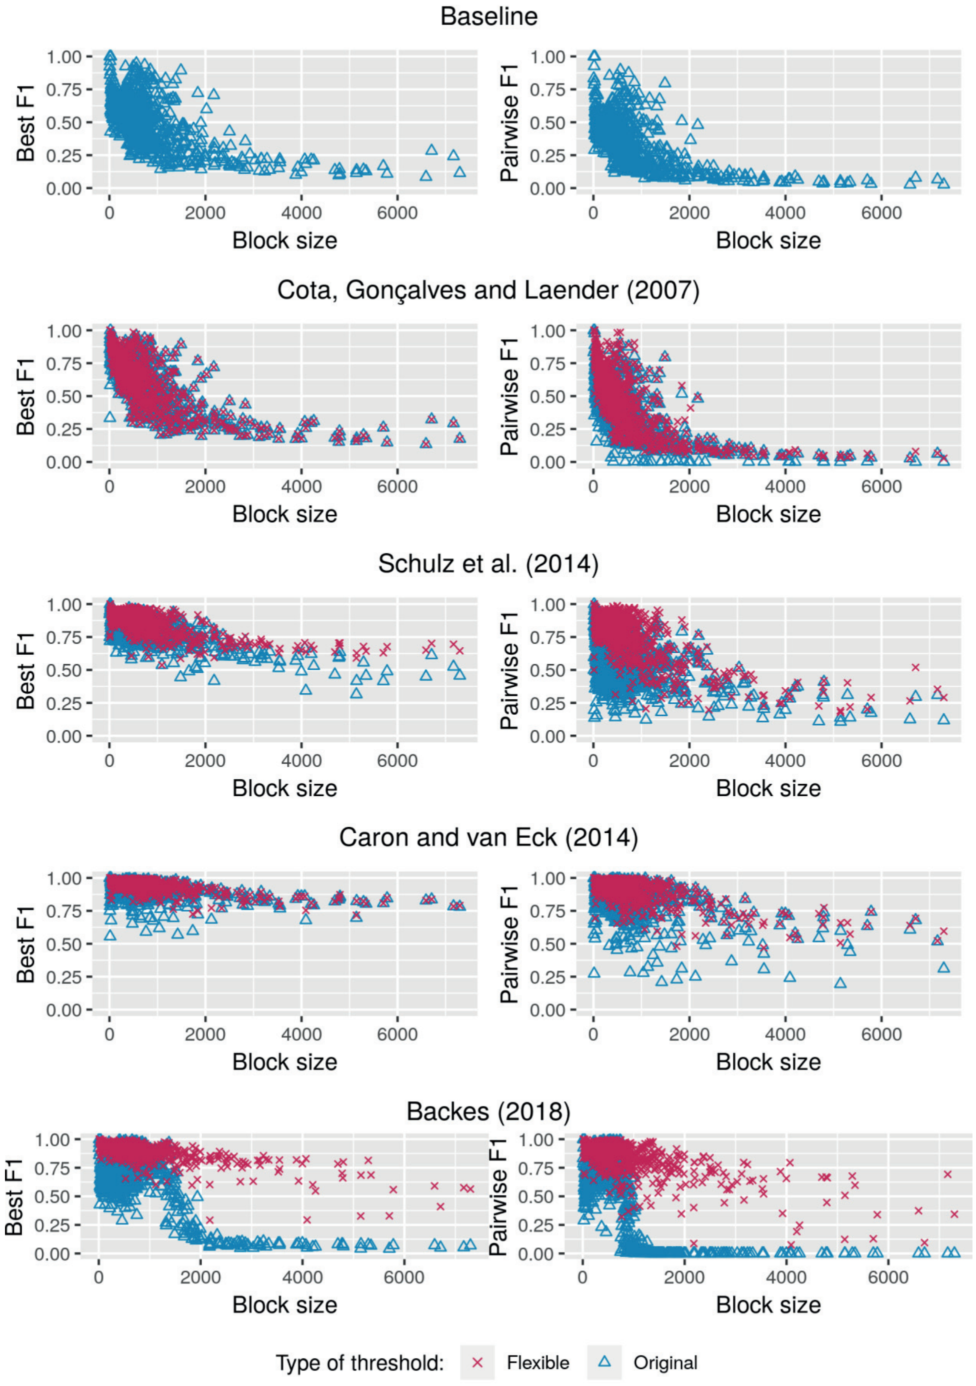
Influence of parametrization on the disambiguation quality

Among the approaches included in our comparison, Caron and van Eck (2014) and Backes (2018) used block size dependent thresholds. As described above, the first approach is based on defining one threshold for each of six block size classes, whereas the threshold is linearly dependent on the block size in the second approach. Table 4 shows the block size classes and corresponding thresholds used by our implementation for the approach of Caron and van Eck (2014). In contrast, the approaches of both Cota, Gonçalves, and Laender (2007) and Schulz et al. (2014) use global thresholds for all block sizes.

Table 4. Block size classes and thresholds for Caron and van Eck (2014)

Block size	Threshold ($\mathbf{F1_{pair}}$)	Threshold ($\mathbf{F1_{best}}$)
1-500	21	19
501-1000	22	21
1001-2000	25	23
2001-3000	27	25
3001-4500	29	25
>4500	29	27

Figure 1. Distribution of disambiguation quality over block sizes



In Figure 1, the results based on optimal thresholds for each single block (flexible thresholds) represent an upper bound for the quality over all possible thresholds. Flexible thresholds would not greatly improve the quality of the approach of Cota, Gonçalves, and Laender (2007) since the results based on global thresholds are very close to the results based on completely flexible thresholds. The reason for this is that the quality is dominated by the first step of the approach, which does not employ any threshold at all. The second step, on the other hand, does not change the results significantly, so that the effect of the thresholds is rather small. In contrast, the approach of Schulz et al. (2014) could benefit from using flexible thresholds, especially for large blocks.

Similar to the approach of Cota, Gonçalves, and Laender (2007), the difference between the original implementation and the one with flexible thresholds is rather small for the approach of Caron and van Eck (2014). However, the choice of thresholds does affect the result in this case, as shown by the comparison with an implementation based on a constant threshold for all block sizes. Table 5 shows the evaluation results for the approach of Caron and van Eck (2014) with three different types of thresholds: a constant threshold for all blocks ("Constant"), the thresholds of the block size classes shown in Table 4 ("Block size classes"), and the optimal threshold for each single block ("Flexible"). These results show that the original implementation produces better results than those obtained using a constant threshold. This means that the somewhat rough partitioning between six block size classes already allows for an adequate differentiation with regard to the threshold, and that this strategy improves the disambiguation result compared to a constant threshold over all block sizes. In contrast, the strategy of specifying a threshold which is linearly dependent on the block size, as employed by the approach of Backes (2018), is unable to find good thresholds over the complete range of block sizes. This is due mainly to a drop in the recall (together with an increasing precision) for large blocks. The thresholds chosen by the algorithm are thus too high for large blocks. Hence, a linear relationship between block size and threshold would not appear to be an adequate strategy for large blocks. The fitted thresholds for the approach of Caron and van Eck (2014) also confirm that a nonlinear relationship between block size and threshold may be more suitable.

Table 5. Results for different types of thresholds for Caron and van Eck (2014)

Type of threshold	P_{pair}	R_{pair}	$F1_{pair}$	P_{best}	R_{best}	$F1_{best}$
Constant	0.690	0.741	0.714	0.879	0.880	0.880
Block size classes	0.831	0.787	0.808	0.916	0.885	0.900
Flexible	0.907	0.850	0.878	0.954	0.897	0.924

The results in Figure 1 and Table 5 demonstrate that the disambiguation quality can be improved if flexible thresholds dependent on the block size are specified. However, the specification of adequate thresholds is generally a non-trivial task since it depends on the data at hand. Likewise, the thresholds proposed previously for the approaches examined in this paper do not correspond to the thresholds fitted with regard to our dataset.

Discussion

The disambiguation of units (researchers, research groups, institutions etc.) for bibliometric analyses is an important topic in research evaluation. The results of evaluation studies can only be as good as the underlying data. For example, Clarivate Analytics annually publishes the names of highly cited researchers who have published the most papers belonging to the 1% most highly cited in their subject categories (see https://hcr.clarivate.com). The reliable attribution of papers to corresponding researchers is an absolute necessity for publishing this list of researchers. Although different disambiguation approaches have been developed and implemented in local bibliometric databases (e.g., Caron and van Eck 2014), there is hardly any comparison of the approaches. However, this comparison is necessary to obtain indicators of the best approaches, or those conditions on which the performance of the approaches depends. In this paper, we compared different author name disambiguation approaches based on a dataset containing author identifiers in the form of ResearcherIDs. This allows a better comparison of different approaches than if previous evaluations are used since these are generally based on different databases. Our results show that all of the approaches included in the comparison perform better than a baseline that only uses a canonical name representation of the authors for disambiguation. Although the comparison does not point to the recommendation of one approach for all disambiguation tasks, it does provide evidence of when which approach can produce good results – especially with regard to the size of corresponding name block sizes. As our analyses show, the parametrization of the approaches can have a significant effect, which depends largely on the data at hand. Therefore, the context of the disambiguation task has to be taken into account for a proper implementation of an algorithm. In the context of this study, the approach proposed by Caron and van Eck (2014) produced the best results.

Future research should further examine how different author name disambiguation approaches behave and how certain features affect the disambiguation results. For example, the set of characteristics used by the approaches may play an important role. Since the approaches included in our comparison use different sets of characteristics, differences in the results may be due in part to the choice of the characteristics used. A more detailed analysis of this choice in future studies may shed more light on which set of characteristics is most suitable for which context.

Understanding how author name disambiguation approaches behave is important in order to improve the algorithms and to assess the effect they have on analyses building on the disambiguated data. A good understanding of the behaviour is the basis for reliable analyses at the individual level.

Acknowledgments

The bibliometric data used in this paper are from an in-house database developed and maintained in cooperation with the Max Planck Digital Library (MPDL, Munich) and derived from the Science Citation Index Expanded (SCI-E), Social Sciences Citation Index (SSCI), Arts and Humanities Citation Index (AHCI) prepared by Clarivate Analytics, formerly the IP & Science business of Thomson Reuters (Philadelphia, Pennsylvania, USA). We would like to thank Robin Haunschild and Thomas Scheidsteger from the Central Information Service for the institutes of the Chemical Physical Technical (CPT) Section of the Max Planck Society (IVS-CPT) for providing the computational infrastructure for conducting our analyses.

Abstract

This paper presents an analysis of the uptake of OA publishing by universities in the Leiden ranking, distributed over five countries. The countries we study are part of a large scale supra-national study on research quality, in which a variety of methods is used. Linking policy initiatives to bibliometric results on OA publishing, based on Web of Science and enriched by Unpaywall data, leads to perspectives on the way the universities across the five countries have different foci on OA publishing. Finally, we will show which are the consequences of the launch of Plan S, an international funder driven policy initiative focused on a certain preferential way of OA publishing.

Introduction

In this paper we present the results of research conducted in the R-Quest project. R-Quest is a project funded by the Research Council Norway (RCN), in which the focus is on research quality as an element of research management and evaluation. The R-Quest project is in its third year, of a 5/8 year stretch. In this particular analysis, we will focus on the aspect of openness of research communication, in other words the uptake of Open Access publishing by the universities as represented in the Leiden Ranking, for the five countries in the R-Quest study (Norway, Denmark, Sweden, the Netherlands, and the UK). We will compare closed with OA published outputs, as well as make comparison between Gold, Green, Hybrid and Bronze OA. We will position these against the national mandates at play, in order to see to what extent universities behave mandate compliant. All of this has been complicated by last September's launch of Plan S, a policy initiative that intents to roll back the relevance of Hybrid OA publishing, as it does not seem to function as transitioning from Closed to Gold OA, as most journals (and thus their publishers) stick to the double dipping situation of toll access, with additional APC based OA publishing in these journals.

Rationale for this analysis

Given where we stand now, one can expect that notions of Open Science, and hence Open Access publishing, will further change the way scholarly communication patterns develop over the next 10-15 years. This means a re-orientation on scholarly work, involving doing research, data sharing, collaboration, publishing and reviewing, etc., but also might change the publishing world (mega-journals and platforms, instead of regular publishers and their journals, as well as the ways research and scholarly work is being funded., and this might all heavily affect the academic reward system. Given all of this, one might expect that Open Science and Open Access will affect notions of research quality, as studied in the project.

OA Policies: mandates of open access publishing

In order to be able to monitor and compare between the five countries in the study, and the universities in the Leiden Ranking, we have to contextualize the developments against the national policy background. In the case of analysis of OA uptake, that means introducing the national OA mandates. OA mandates can be defined as the policies adopted by research institutions, research funders, or government, requiring research communities (which is usually university faculty or research staff and/or research grant recipients) to make their published, peer-reviewed journal articles and conference papers available as Open Access (Harnad et al, 2004). Most Open Access (or nowadays Open Science) mandates distinguish various forms of OA publishing. Green OA publishing is a first variation, which consists of the (self-)archiving of final, peer-reviewed drafts in a freely accessible institutional or disciplinary repository. A second variation is Gold OA, which means publishing your manuscripts in fully open access journals, with or without paying APCs (Article Production Costs). A third variation, mostly not mentioned in OA mandates, is the hybrid form of publishing your manuscripts, in an open access format in an otherwise toll-access journal (this is called the hybrid format of OA publishing). A fourth type of OA publishing, which will be considered here is Bronze OA, a type first reported on by Piwowar et al (Piwowar et al, 2017), and further analysed on a large scale by Martin et al (Martin-Martin et al, 2018).

The five countries in the study have each their own, specific OA mandates. The Norwegian OA mandate is focused on Green OA, preferably via institutional repositories, with no explicitly defined goals in time to reach a full 100% OA Norwegian output. In the Netherlands, pressure is somewhat higher, as there the focus is on Gold OA, with science policy explicitly stating terms when the full 100% has to be reached: initially the planning spoke of 60% in 2018, and 100% in 2024, which is shortened to setting the 100% goal to be reached in 2020. This would apply on journal publishing only, as it is recognized that book publishing is somewhat more complex. In Denmark, like in Norway, the focus is mostly on Green OA publishing, irrespective in what type of repositories, with no hard goals set in time to reach a full 100% OA uptake. In Sweden, the national OA mandate is quite free, as there is no explicit preference for either Green or Gold OA, the only requirement relates to having a CC-BY license, which allows re-use of the information. There are no goals set in time, to reach a full 100% OA uptake by the Swedish research communities. However, books and chapters are exempted from this policy, as there is a strong realization that the change in business models with respect to that type of scholarly communication and hence the publishing of those forms of communication might take more time. Finally, in the UK the focus is on Gold OA, with the explicit requirement that in the next Research Excellence Framework (REF) exercise only (Gold) OA published material is to be accepted as underlying the assessment procedure. So here we clearly distinguish various perspectives on both the type of OA publishing, as well as the time path involved in which this has to materialize.

Recent policy developments involving OA publishing: Plan S

In September 2018, Science Europe launched Plan S, a policy initiative to further stimulate the publishing in open access format of results of scientific/scholarly work. The initiative was taken by a coalition of supranational and national funders, from a number of European countries. The plan basically prescribes the researchers that profit form a grant from their agencies, to publish the resulting outcomes in open repositories, platforms, or journals that are open and stay open, all to be realized by 2020. The plan mentions a number of principles, with the major, overarching principle being that research outcomes from public grants must be published in open access journals or platforms. An important incentive for this development was the dissatisfaction of policy with the pace of the OA uptake and development. The type of OA publishing that was intended to signal a transition period ("hybrid" OA), is seen as an attempt by the publishing industry to stall the process of transition. Therefore, hybrid OA has to further change into either Gold or Green OA. Consequently, any reactions from the publishing industry, to create mirror journals for the toll access journals is considered as non OA, and non-Plan S compliant, unless there are clear transformative agreements with the respective publishers for the future development of the respective journals into a further opening up.

Creating OA tags in the Web of Science

Until recently, the Web of Science (WoS) disclosed only in a limited sense OA labels related to indexed publications (van Leeuwen et al, 2018). Of a more recent nature is the implementation of the Unpaywall dataset on WoS. Before this current study, we have developed a methodology developed within CWTS, based upon freely accessible/no costs involved data sources, as we reported on in previous work (van Leeuwen et al, 2017)[1]. This methodology has a clear drawback, namely that it is not possible to distinguish within the OA published material, the Green OA published material from the Hybrid OA published material. However, an important advantage is the high level of control on how OA tagging of WoS indexed publications occurs. In the development of this method, we defined two criteria, namely that of ***sustainability*** (data are in the public domain, without immediate and direct risk of disappearing behind a pay-wall), and ***legality*** (inclusion in the data source should not be based on 'illegal acts' by individual researchers, so no copy right breaches involved).

The source we used for this analysis is Unpaywall. The inclusion of Unpaywall in our database of WoS indexed publications, will also lead to analyses to compare both methodologies, and the degree of complementarity in both directions, that is the direction of the methodology to tag OA developed by CWTS (however, that is beyond the goals of the current study and will be reported elsewhere). The implementation of Unpaywall would allow us to identify hybrid OA, which is extremely important in the light of discussing the consequences of Plan S, a recently launched policy initiative to take out hybrid publishing from the OA landscape, as it does not promote a further transition of academic publishing into a full OA situation, as well as Bronze OA. This type of OA publishing, in which the publishing industry initiated OA availability of published material, is only partially compliant to the criteria defined, and described above, namely compliant with the legality criteria (as no copy rights are breached, these remain with the publisher instead of the authors), but not compliant with the sustainability criteria (as the publishers can decide at any moment what contents will be available OA). It is important to note that the other types of OA publishing, Gold, Green and Hybrid all involve a certain degree of engagement or involvement of the academic actors in the science system (e.g., researchers/authors, librarians). A description of the methodology on tagging the publications in the Leiden Ranking can be found at the CWTS Blog (van Leeuwen et al, 2019).

Data on Leiden Ranking of universities for the R-Quest countries and the universities

Within CWTS, we can access the list of universities that are presented via the Leiden Ranking. In this case, we selected for the five countries in this study all publications related to these universities, and could do a re-run of the basic indicators available in the CWTS tool box of research metrics. Analyses focusing on the OA uptake within the institutional setting

[1] The sources we used in the study are the DOAJ and the ROAD lists of Gold OA journals, which together span the universe of Gold OA publishing, while the CrossRef, PubMedCentral, and OpenAIRE databases functioned as sources to determine Green OA in the WoS database. In linking sources to the database, we used various identifiers, such ISSNs for the Gold OA journals, DOIs for the other three databases, PubMedIDs for PubMedCentral data, while we also applied a fuzzy matching algorithm to link OpenAIRE to WoS. These five sources complied with both our criteria of sustainability and legality. Two sources that did not comply with our second required criteria are SciHub and ReserachGate, as these sources consistently show breaches of copy right.

have not been conducted in similar comparative fashion before until recently (Bosman & Kramer, 2018). In our analysis we will use the national mandated situation as a proxy for the institutional settings, rather than compare the institutional attitude towards OA for every single university in our analysis with their OA publishing uptake. We worked with three indicators: the number of publications, which is actually the number of normal articles, reviews, and letters as processed for journals covered in the Web of Science database, in the period 2014-2017/2018. On the basis of this set of selected publications, we calculated mncs and mnjs scores (Waltman et al, 2012). MNCS stands for the comparison of the real impact of a set of publications with expected citation scores, based upon output similarity in the exact same fields, years, and documents, while mnjs stands for the comparison of the impact of journals selected for publishing with the expected field citation impact, based upon output similarity in the exact same fields, years, and documents. We selected mnjs as well, not being a standard indicator in the Leiden Ranking, as this indicator informs us about the choice of journals with a certain prestige/reputation/standing in the fields to which these journal belong.

Results

To start the description of results, we first need to describe how the level of analysis is constructed. In Table 1, the second column the number of universities from the respective countries in the Quest study, as represented in the 2018 Leiden Ranking (LR 2018). We refer to these in an aggregated manner, by using the label "national/institutional" as the variable that represents at the national level in each of the five countries, for only these LR 2018 universities.

The next columns in Table 1 contains the aggregate numbers of publications for the universities in the study, in the various formats in which the output can appear in the journals as processed for the WoS. So we first present the Closed format output, followed by Gold OA, Green OA, Hybrid OA, and bronze OA. As stated before, we do not consider Bronze as a sustainable type of OA publishing, we report it though for reasons of completeness.

Table 1: Overview of numbers of universities in the study, and the national/institutional distribution of output over types of OA, 2014-2017/2018

	Nr Leiden Ranking universities	*Closed*	*Gold*	*Green*	*Hybrid*	*Bronze*
Denmark	*5*	*27108*	*8971*	*27634*	*5064*	*6839*
Netherlands	*13*	*64740*	*19946*	*61418*	*18623*	*15475*
Norway	*5*	*16254*	*6126*	*15305*	*3801*	*3286*
Sweden	*11*	*44418*	*15094*	*41375*	*11814*	*9653*
United Kingdom	*48*	*106599*	*45711*	*193623*	*55493*	*30178*

In Table 2, we present the relative situation, the shares per type of publishing for the five countries LR 2018 covered universities. Please note that due to choosing for the full picture, whereby overlapping forms of OA publishing are made visible (see van Leeuwen et al, 2019), percentages do not sum up to 100%, due to the double counting of publications mostly under Green OA. The share of OA published or available OA output for the UK is clearly higher as compared to the other four countries.

Table 2: Overview of the national/institutional distribution of shares of the output over types of OA, 2014-2017/2018

	Closed	*Gold*	*Green*	*Hybrid*	*Bronze*
Denmark	*46%*	*15%*	*46%*	*9%*	*11%*
Netherlands	*47%*	*14%*	*44%*	*13%*	*11%*
Norway	*47%*	*18%*	*44%*	*11%*	*10%*
Sweden	*47%*	*16%*	*44%*	*12%*	*10%*
United Kingdom	*33%*	*14%*	*60%*	*17%*	*9%*

If we look at Figure 1, which presents the contents of Table 2 in a graphical manner, we clearly observe that all five countries have roughly 50% or more of the output in OA format published or available in 2014-2017. We carefully mention here ’available’, as we want to make clear by choosing this wording to indicate that with respect to Bronze OA, this is not authors’ choice, but rather publishers’ choice, while the other OA format types are clearly an effect of authors’ choice. Given the fact that this involves some 10% of the national/institutional outputs of the countries involved, this is not a neglible part of the national/institutional outputs in OA format.

Among the five countries in this study, the largest share of OA published/available output is observed for the UK. Some 60% of all output in 2013-2016 are in some form of OA format, compared to some 50% for the other countries and their LR 2018 covered universities.

A rather surprising outcome is the low share of output published via the Gold OA route: all five countries cover about 10/15 % of the national/institutional output in this OA type, which is all the more remarkable since two of the five countries have made this explicit target in their national OS/OA mandates, namely the UK and the Netherlands. And although Green OA is not the explicit preference for the UK, we observe for the UK the largest share of their national/institutional output as published via the Green OA route (60%). A more or less equal situation exists for Denmark, although here an explicit reference was made to Green OA in the national Danish OS/OA mandate (18%). For the other three countries, Green OA is equally developed (about 45 %). For all five countries and their universities studied, we observe a strong preference for Hybrid OA publishing, a situation we will delve into more deeply in the next section. Finally, what is made available via the publishers as Bronze OA varies around 10% for the five countries in the study.

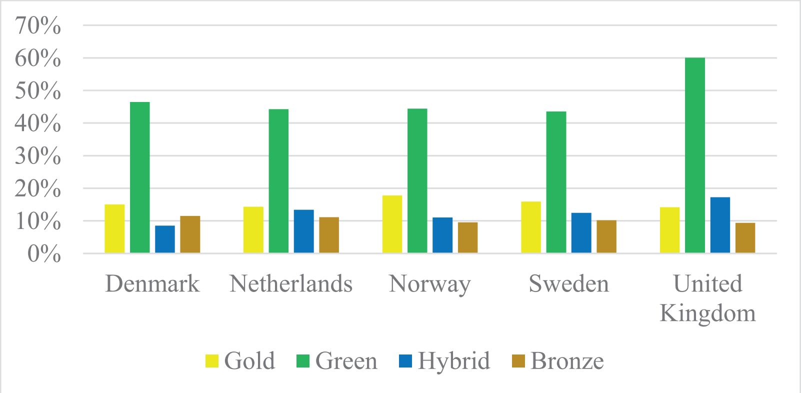

Figure 1: National/institutional distribution of output over types of OA publishing, 2014-2017/2018

If we shift our attention towards the way the five countries in the study have taken up the so called CWTS compliant OA forms, as displayed in Figure 2), we clearly see that for four countries (Denmark, the Netherlands, Norway, and Sweden), the share of the total publication output is varying around 45%, while for the UK this is around 60% in the period 2014-2016/17. Please note that this consists of Gold OA, Green OA and Hybrid OA only.

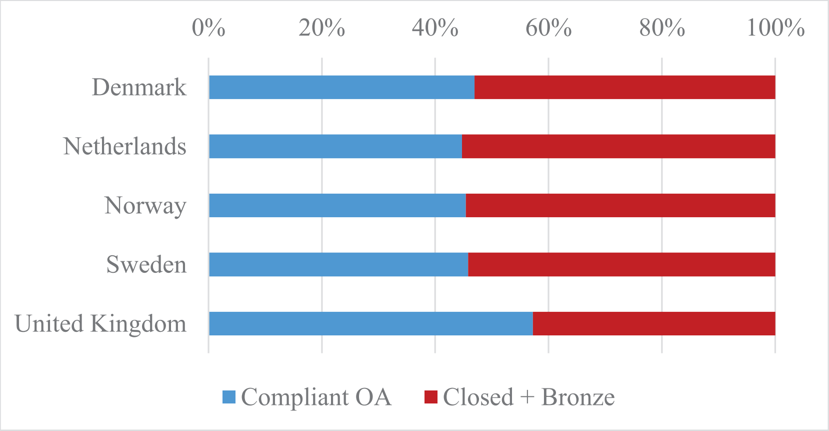

Figure 2: National/institutional distribution of output over OA vs non OA publishing, 2014-2017/2018

In Figure 3, we apply the philosophy of Plan S, thereby taking out Hybrid OA format published materials, as not compliant with Plan S, and thereby no longer policy relevant when in comes to understanding the uptake of OA publishing in the universities in the five countries in the study. We then notice a slight decrease in shares of OA published outputs from the country/institutional setting, a situation that sets back the shares of OA publishing to varying around 40%, with the Netherlands, Norway and Sweden slightly above that 40%, and Denmark around 45%. The UK then ends up with some 55% of the national/institutional output being published in Plan S compliant journals.

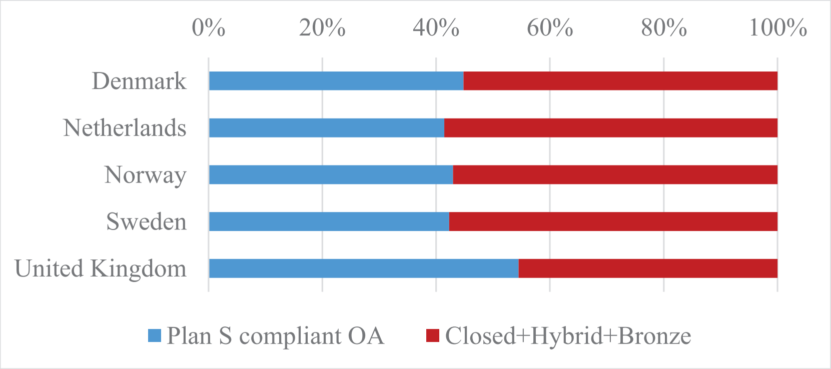

Figure 3: National/institutional distribution of output over Plan S compliant OA vs non OA publishing, 2014-2017/2018

What is important to note here, is the relative small difference between the two types analyses, as we clearly observe that the proportion of Hybrid and Bronze OA is decreasing, while on the other hand Green OA is increasing. Green OA overlaps strongly with these two types, so in that respect, the effect of the implementation of Plan S will have little effect on the overall uptake of OA publishing, while still keep in mind that these figures are mainly influenced by the increase of Green OA, rather than Gold OA (the main goal of Plan S, full and immediate access via Gold OA journals).

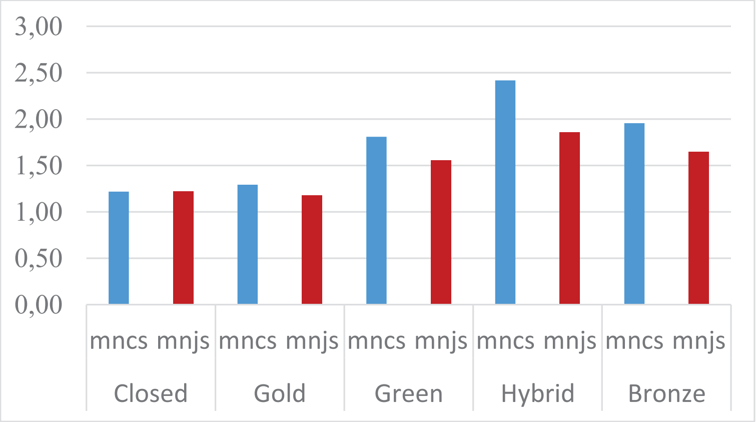

Figure 4a: Impact scores (mncs, mnjs) related to national/institutional distribution over various OA output types for Denmark, 2014-2017/2018

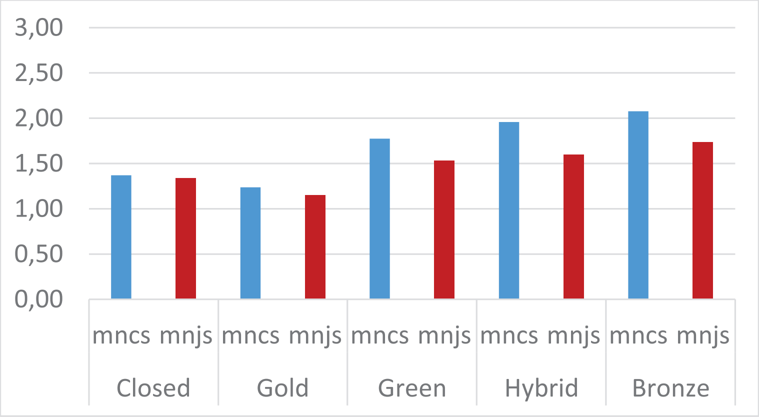

Figure 4b: Impact scores (mncs, mnjs) related to national/institutional distribution over various OA output types for the Netherlands, 2014-2017/2018

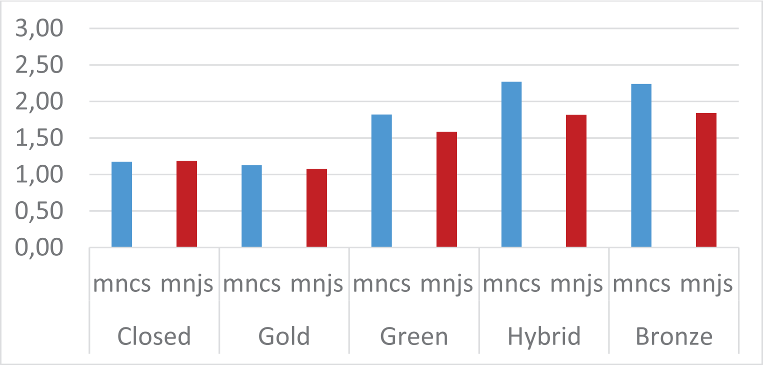

Figure 4c: Impact scores (mncs, mnjs) related to national/institutional distribution over various OA output types for Norway, 2014-2017/2018

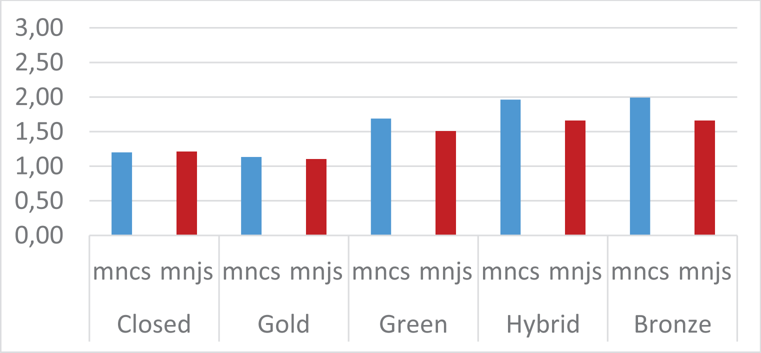

Figure 4d: Impact scores (mncs, mnjs) related to national/institutional distribution over various OA output types for Sweden, 2014-2017/2018

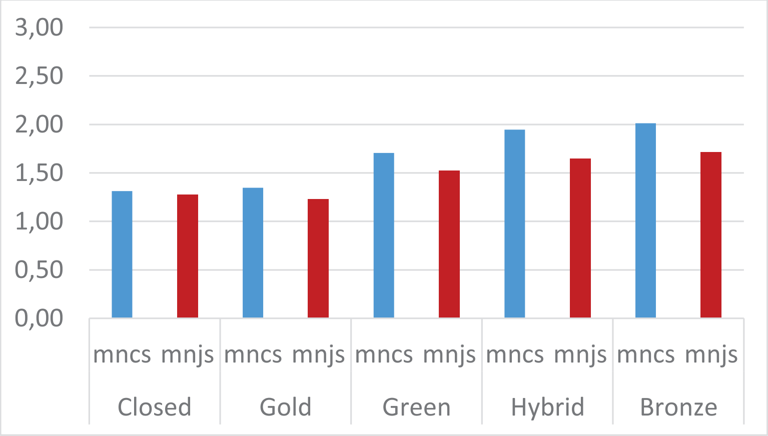

Figure 4e: Impact scores (mncs, mnjs) related to national/institutional distribution over various OA output types for the UK, 2014-2017/2018

If we then add citation impact measures to the analysis, we can create overviews as displayed in Figure 4a-4e. In these figures 4a-4e we present for the five countries the national/institutional citation impact analyses, by type of publishing. In each graph we present the output that was published in non OA format ("Closed"), as well as the Bronze OA output, the Gold, Green and Hybrid OA format output. The impacts score mncs (blue bar) expresses the actual normalized impact over the whole body of publications per type per country/institutional set of publications, while mnjs (red bar) depicts the level of the impact of the journals which were chosen for publishing, compared to the field(s) into which these journals belong.

A first observation relates to the impression of overall impacts. The five graphs clearly show that outputs from the universities as covered by the LR2018 all produce impact levels that are, even considered across all types of publishing, as above worldwide average impact level (with the value one representing worldwide average impact level). A next observation is that in all five countries, Closed published outputs compete with Gold OA for retrieving lowest impact values. This clearly indicates that both the actual impact, as well as the journals chosen for this set publications, is not having the highest standard, with the Netherlands and Sweden as cases in which the impact of Gold OA published outputs is even somewhat lower as compared to the Closed published output. A third observation is that Hybrid and Bronze OA published outputs are reaching high impact scores on mncs. Denmark is the country where Hybrid OA published output reaches the highest impact level, both overall as for the journals selected to publish in. For Sweden, Norway and the UK, the impact levels on mncs are equally high for Hybrid and Bronze OA, while for the Netherlands we observe that Bronze OA output reaches highest impact level. A fourth observation relates to the impact levels of the journals in which the Green and Hybrid OA format output was published: for the Netherlands, Sweden and the UK these reach mnjs values varying around the value of 1.5 for both Green and Hybrid OA. For Denmark and Norway, the differences between mnjs values of Green and Hybrid OA outputs are somewhat larger. These high impact levels for these two types of OA publishing are important, as this is indicative of high impact level journals in the fields to which these belong, an observation which would probably correspond to these journals being published in journals with relative high JIF values (van Leeuwen and Moed, 2002). This is important, as the JIF plays an important role in the discussion in Plan S about perceived journal quality (expressed by high JIF values), and the way that might influence academic careers. A final observation relates to the Bronze OA type of publishing. Here we clearly see that this publisher initiative based OA form is having high impact scores. Clearly, publishers use these publications to showcase their journals, and the strength these journals have in the respective fields these journals belong to. In all five cases, the displayed outputs in Bronze OA format have the highest impact scores, compared to the other four types of academic outputs.

Discussion

This study shows the uptake of OA publishing in the five countries under study in the RCN funded research project R-Quest. This particular analysis focuses on the level of universities, as represented by the Leiden Ranking 2018, and the way these universities (in an aggregate fashion) perform on the various types of OA publishing. As the notion of research quality is central, this study evolves around the way Plan S effects the OA uptake, and the potential effects this policy initiative has on the way OA publishing is taken up in the universities in the five countries in the study. As Plan S aims at diminishing the hybrid form of OA as a way to publish findings in an open access format, this study tries to unravel the various forms of OA publishing, versus impact measures connected to the various forms of publishing.

The tense reactions by academic communities in the countries connected to Coalition S, the funding agencies that joined forces to implement Plan S, shows the complex relationship between perceived quality of journals, as reflected by high JIF values, and in this study represented by mnjs values, and notions of research quality. The disappearing or diminishing of possibilities to publish hybrid OA, means limiting the opportunities to publish in journals with a relative high level of prestige or reputations, as reflected by high JIF values. This indicates that in the transition phase we are currently, in academia, towards a system of full open science based working environments, notions of research quality are potentially repeatedly re-defined, and might be highly volatile for a period of time.

This study also signals some methodological issues. A first issue to mention in this respect is the fact that more sources become available that backwardly declare outputs as Open Access (journals being included in the DOAJ, and thereby being treated and counted as OA, although at the moment of publishing not being OA, or vice versa, journals that previously be on the DOAJ list, and have now disappeared from that list). A second issue is the fact that datasets such as WoS and Scopus lack certain unique identifiers for early years, thereby creating issues related to 'gaps' in what was actually OA, or could have been counted as OA (the missing DOIs in earlier years of our WoS subscription caused this type of problems, only recently resolved by Clarivate Analytics).

A conceptual issue that keep returning is the definition of the various types of OA publishing, and the way these various forms are being treated as policy relevant or not. The Unpaywall database has solved many of the problems in defining OA publishing types, while the way OA publishing forms are considered as policy relevant is much less stabilized or clearly defined. In future research we will try to come up with potential solutions to this problems as well.

Abstract

The characteristics of patents are different from academic papers, classical citation analysis methods may not be suitable for patent analysing. Identifying the textual features of patents accurately is still challenging job. Recent deep learning techniques brought human-competitive performances in various tasks of fields, including image recognition, natural language understanding etc. In this work, we build a set of processes for feature extraction, clustering and visualization of technology structure discovery using machine learning model. First, we trained an unsupervised patent features extraction model (Pat2Vec) which learns the properties from millions of patent texts in high-dimensional vector space. Then we clustered 291,493 Triadic Patent Families from 2012 to 2017 in vector space to classify the technology structure. Finally, we visualised the large-scale relationship of the patents and clusters of patents using the LargeVis algorithm. The analysis results show that the feature extraction accuracy of Pat2Vec is higher than the traditional text feature extraction model. The technology structure map obtained by clustering patents provides the possibility for further analysis.

Introduction

A World Intellectual Property Organization (WIPO) report points out that almost 90-95% of the world's R&D outcomes are covered in patent publications with the remaining 5-10% reported in the technical literature (essays and publications) (Liu & Yang, 2008). In order to understand the world's technological innovation layout, discover the emerging or hot technologies, it is necessary to discover the structure of technology, which mostly represented by patents.

It is different from the patent citation and the citation of the academic paper, the motivations of citation by the applicants and the examiners are also different. In addition, the citation of the patent is very sparse if we compare them with the papers. According to our statistics, less than 30% of the triadic patents in the past six years have direct citations, and 37% have co-citation relationships. Therefore, the classic citation analysis method in patent analysis may lack some important patents. The commonly used patent IPC, USPC classification is mainly based on functionality, sometimes difficult to correspond to the industrial technology classification. Besides the classification system is usually updated very slowly, unable to reflect the key technologies' latest changes. Content-based patent analysis can avoid the defects of citation relations, but most of the content analysis is based on the keywords or key phrase, which may have the problem of polysemy, it makes the accuracy and usability of text analysis not very efficient. Therefore, how to improve the accuracy of patent content analysis is still a challenge. Recent deep learning techniques brought human-competitive performances in various tasks of fields, including image recognition, natural language understanding etc. This study tries to use Doc2vec model to train the patent feature vector model Pat2Vec and get technology structure more accurately and usefully.

Related work

Existing studies using patent maps to describe the global technical structure mainly include: 1) SCITech Strategies garnered a scientific map containing 20 million papers and 2 million patents (https://www.scitech-strategies.com/). The map contains the largest number of patents, and the patent relationship is mainly established by the citation relationship between the patent and the paper. The practical application of the patent map has not been found yet. The main problem of the patent map is missing some patents because of using patents and papers citations relationship; 2) Japan's JST uses Top1% high-cited patents for co-citation clustering to generate technology front (Jibu, 2014). The problem with this map is that valuable front-end patents are not necessarily to be the highly cited patents, and similar patents do not necessarily have a citation relationship between them. 3) Clarivate Analytics' Derwent Innovation platform produced a patent map using key term co-occurrence relationships, the main drawback of term co-occurrence relationships which are described above.

Several other studies have been tested to automatically extract topic classification using latent Dirichlet allocation (LDA) (Blei, Ng & Jordan, 2003). In essence, the topic is usually a cluster of keywords. It is sometimes difficult to determine the specific topic represented by the group of keywords because the intersection of similar keywords between the topics.

In 2013, Word2vec was created by a team of researchers led by Mikolov et al. at Google(2013a, 2013b), it takes as its input a large corpus of text and embed them into an vector space, typically of several hundred dimensions, embedding vectors created using the Word2vec algorithm have many advantages compared to earlier algorithms such as latent semantic analysis.

On top of Word2vec, Doc2vec or Paragraph2vec (Le & Mikolov, 2014), Sentence Embeddings, is an unsupervised algorithm that can obtain vector representations of sentences, paragraphs, or entire text, and is an extension of Word2vec. Compared with the Word2vec model, Doc2vec adds a paragraph matrix in the process of training the word vector, which is more suitable for the text length of the patent text title abstract.

Data

According to the "World Intellectual Property Indicators 2018" published by WIPO, in 2017 global innovators submitted a total of 3.17 million patent applications, which achieved growth for the eighth consecutive year. However, the value distribution of patents is not balanced, and many patents have lower value. In order to avoid excessive patent noise to impact analysis results, this study selected "Triadic" patents for analysing.

Triadic patents are a series of corresponding patents filed at the European Patent Office (EPO), the United States Patent and Trademark Office (USPTO) and the Japan Patent Office (JPO), for the same invention, by the same applicant or inventor (OECD, 2005). Since the United States, Japan, and the European Union are the three most important markets in the world, and the patent application and maintenance costs are high, triadic patents are generally considered to have high economic value, it may be able to reflect the value of a country's technological invention and competitiveness in the international market.

This study selected 291,493 triadic patents from 2012 to 2017 as the analytical data set, with the patent family as the smallest analysis unit. 3 million patents from US Patent Office were used as training data for model.

Methods

The research flow of this study is shown below. In order to explore the law of patent texts, a doc2vec model start learn text representation of patent from 3 million USPTO patents, then the triadic patents text is placed in the semantic model to extract the text vector features of each

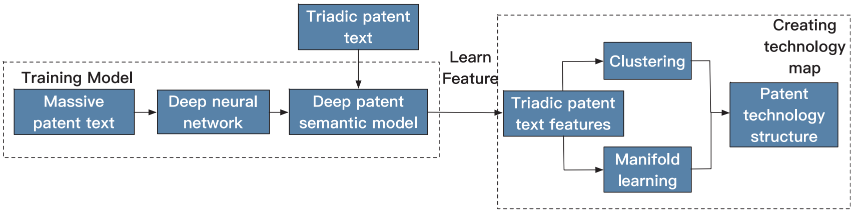

Figure 1 Method flow chart

triadic patent. Finally, the patented technical structure is discovered through clustering, and the relationship between patents is visualized through the large-scale manifold learning model.

Patent feature extraction model based on massive patent text training

The patent's feature extraction model mainly uses the Doc2vec model based on neural network embedding model. We use more than 3 million patents from USPTO in 10 years, mainly using the title and abstract to train the model, we call this model Pat2Vec. Before we train our model, we applied standard NLP pre-processing, such as removed punctuation and stop words, then applied lemmatization and Stemming to patent text. The training algorithm of the model is distributed memory (PV-DM), it acts as a memory that remembers what the topic of the paragraph is. While the word vectors represent the concept of a word, the document vector intends to represent the concept of a document. The PV-DM model is superior and usually performed better than another model Distributed Bag (PV-DBOW).

Clustering based on patent feature vectors

The triadic Patent text feature produced by Pat2vec model is a 100-dimensional feature vectors. In this study, we directly cluster patents in the feature vector space instead of converting the feature vector back into the similarity matrix and then do the community detection. Because compared to community discovery in the network, the technology is more mature and accurate to use traditional machine learning clustering in the feature space(Goyal& Ferrara, 2018; Gunasekaran et al., 2017). We tried hierarchical clustering and spatial partitioning clustering algorithms. Since the quantity of triadic patents is close to 300,000, we choose the fastest K-means clustering algorithm.

Visualization method

When the high-dimensional feature vector of the patent is converted into a distance-based network relationship, there is a loss of information. Based on our visualization study (Chen et al., 2018), the manifold learning based dimensionality reduction visualization model can visualize high-dimensional data better than convert data into the distance-based graph.

The map of massive data usually shows the layout on the topic level. Many articles in one topic are displayed as a point in the map. Since the topic may be large or small, it may affect the visualization effect. This study attempts to create a map with single patent as the basic unit to show the patent layout from the micro level, reflecting the more details of the technology layout. Based the patent level map, construct clustering level map by the location of patents in the subject. The two maps with hierarchical are consistency.

Nearly 300 thousand patents exceed the t-SNE (Maaten & Hinton, 2008) algorithm's computing limit, so this study uses the big data visualization algorithm LargeVis (Tang et al., 2016) for creating a large map based on patent level visualization. LargeVis improved the operation speed of t-SNE algorithm, reduced the complexity of the algorithm from nonlinear to linear, and greatly improves the speed of dimensionality reduction.

Experiments and evaluation

Patent text feature extraction

The test data set was constructed based on the patent classification IPC code. We selected two patents that belong to same subgroup of IPC as similar patents, and then randomly add a patent outside the subgroup but belonging to the same larger group, we treat the third patent as noise. After that, different feature extraction models were used to determine which two patents in the three patents are closer, and whether the noise can be accurately identified. We randomly constructed 4000 sets of triplets to verify the patent feature extraction effect of the Doc2vec model. Experiments show that the feature extraction effect of the Pat2vec model is much better than the traditional models.

Table 1 the accuracy of feature extraction models

Model	Accuracy
Pat2vec	**86.5%**
Tf-idf	73.3%
LSA	76.9%
LDA	78.1%

Clustering parameter selection

The K-means clustering algorithm needs to specify the number of clusters K before clustering, but determining the number of K has always been a challenge. In this study, Sum of squared error, Calinski-Harabasz Index, Davies-Bouldin Index, and Silhouette Coefficient were used to optimize the number of K. The curves of the first three evaluation algorithms start to converge when K=800 to 1200. If the number of patent topics is only 1200, this does not meet the expert's understanding of the patent topics. The Silhouette Coefficient curve increases with the number of clusters and exhibits multiple peaks at K=700, 6400, and 8100. Combining expert judgment with subsequent analysis needs, we choose K=6400.

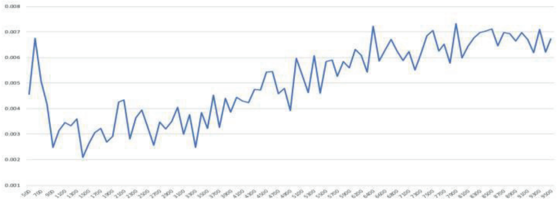

Figure 2 Silhouette Coefficient curve

The clustering results have been interpreted by experts from several fields. The experts believe that the patents in the topic are relatively consistent.

Comparison of patent topics visualization

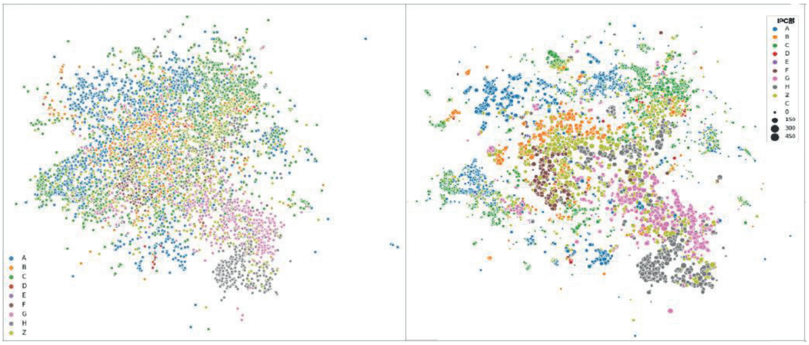

Figure 3 Two clustering representation point algorithms, the left is the intra-cluster coordinate averaging algorithm, and the right is the intra-cluster coordinate density maximum area averaging algorithm.

To construct a coordinate position of a technology topics based on each patent location. This study has tried two methods, first way is using the average coordinates of the patents in the technical subject clustering. Second way is using the average position of the highest density coordinates, as shown in Figure 3. The first method is affected by the uneven coordinate point distribution, and the distribution of the topics in the map is uniform, the aggregation effect is poor. In the second method, the topics has better aggregation and a clearer outline.

Discover the Technology Structure

We map the structure of technology by the relationship of nearly 300 thousand patents (Figure 4). The colour in the left figure is the IPC classification. It can be seen that there are clear separations between different patent IPC classes at the global structure. At the local structure, the sub-topics inside the same IPC classes are also relatively clear.

The colour on the right is the fields obtained by combining the technical classifications of WIPO's 35 fields. As can be seen from the figure, the map can discover the local structure accurately. For example, the class of "Electrical machinery, apparatus, energy" is divided into four large groups: lithium-ion battery/fuel cell, electric vehicles/electric power, electric motor/permanent magnet, and electrical connector.

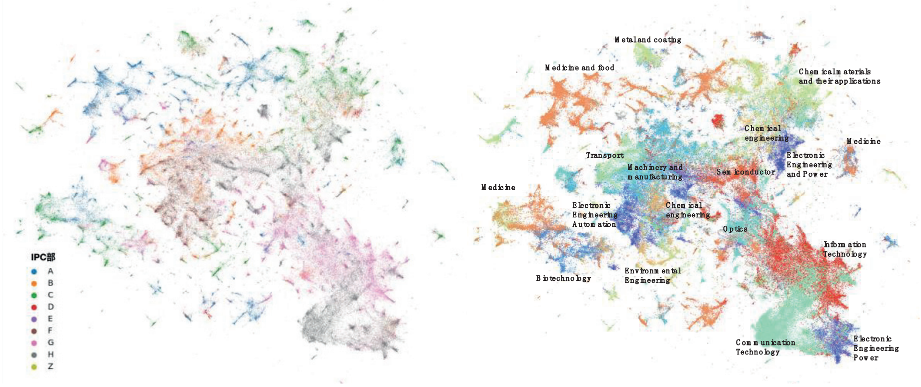

Figure 4 World-wide triadic patent structure map 2012-2017

We further created a heatmap based on patent topics level, the darker area represents higher density of patents in unit area (Figure 5). From the figure, communication and information technology are the areas with the highest density, and the most competitive field in all countries. The number of topics is large, and the average number of patents in the topics is over 70. The next highest dense areas are machinery and manufacturing, optical semiconductors. The areas related to biomedicine and organic chemistry have the lowest density. Although the number of topics in these areas is the largest, but the average number of patents within the topics is the least, only about 20 items in each topic.

In future, we will further analyse the patent layout of countries and institutions based on the patent technology map.

Discussion and future work

We used the machine learning technology to detect and visualize the technical structure of nearly 3 million patent families. A large number of patent texts were used for training the patent text feature extraction model Pat2Vec, to explore the hidden deep relationship and between patented technologies, which improves the accuracy of traditional patent feature extraction model. In order to reduce the loss of information, this study no longer uses the traditional community detection based on distance between patents but clustering directly in high-dimensional vector space; A direct dimensionality reduction method based on manifold learning is adopted to display patent topics level and patents level.

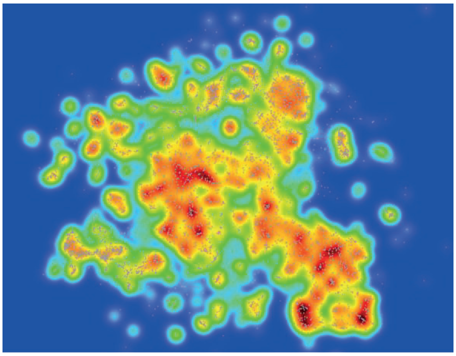

Figure 5 Technology structure heat map

The Pat2Vec model has good versatility and can be applied to other patent data sets and other types of data such as funds, standards, etc. Furthermore, we will build more test datasets for accurate testing and find more accurate patent feature extraction models, clustering models and visualization methods by combining multiple heterogeneous features. After that, we will start researches on the technology hotspots and emerging technology detection based on the technical structure map.

Abstract

The direct contribution of professors and researchers employed by Universities and Public Research Organizations has been emphasized as increasingly important sustain nations' technological edge. We quantify this phenomenon according to a new methodology in a systematic nation-wide empirical investigation over an eighteen-year period. We find that academia (professors and researchers at universities and PRO) account for more than ten percent of all the nation's patents. We estimate that nearly twenty percent of the sixty-one thousand French faculty members, researchers and engineers whose patenting behavior we investigate have invented at least one patent. As a series of policy reforms of the academic sphere have been introduced in France toward implementing the post Bayh-Dole US style of IP management, we appreciate how this translates into modified behaviors of the different players (professors and researchers and universities). In particular, we find evidence for a transitory learning phase of universities after the introduction of the 1999 Innovation Act.

Introduction

In 1980, the Bayh-Dole Act is introduced in the US with the intention of fostering the transfer of technology from universities to the private sector. Through this legislation, the federal government waives to the universities the intellectual property rights (IPR) over federally funded inventions. It contributed to an increase in academic patenting (Mowery et al., 2001) and despite the initial concern (Trajtenberg, Henderson & Jaffe, 1997), Mowery & Ziedonis (2002) conclude that the overall importance of these inventions did not decrease.

The commercial success of the US stimulated several European governments to introduce reforms in order to converge toward the university ownership regime. In some countries as Germany (Czarnitzki et al., 2015), Norway (Hvide & Jones, 2018) or Finland (Ejermo & Toivanen, 2018), the end of the professor privilege had a negative impact on academic invention. Thus, the apparently same ownership model provides contrasted evidence as regards its effect on academic invention on both sides of the Atlantic.

In order to reconcile this contrasted evidence, Geuna and Rossi (2011) suggest that comparing the US reform with the European ones is misleading. Whereas the Bayh-Dole Act transferred the IPR from the federal government to universities, hence making the management of IPR *closer* to the inventor, the end of the professor privilege in European countries made the IPR management *further away* from her.

Another natural explanation is that the IPR management is a complex activity that requires time, financial support and capabilities to be performed efficiently (Grimaldi et al., 2011). Universities and PRO may need to learn how to manage IPR. In the US, Mowery, Sampat & Ziedonis (2002) observe that it took 15 years to US universities without previous IPR management experience to produce inventions of similar importance to those by experienced universities. On the reverse, Hvide & Jones (2018) observe that in Norway the gap in terms of importance between academic and non-academic patents is widening after the reform. Hence, they do not find supportive evidence for such learning effect. It may be because they observe patenting activity only seven years after the reform. It could also come from an insufficient financial support from the government to public universities.

We use the French case to examine the existence of a learning effect after a Bayh-Dole type reform is introduced and meanwhile how universities cope with the reform requirements in practice. France is a particular case as the universities ownership model has always prevailed but in practice universities used to waive a large part of their IPR to companies. In 1999, on the belief that academic invention was weak as compared to the level of investment in fundamental research, the government voted the Innovation Act. Its goal was to incentivize universities to increasingly retain the ownership of its inventions.

We build a dataset on all French professors and researchers (approximately 65,000 persons) and their patenting activity from 1995 to 2012. We observe that 15% of them invented at least once over the period. The overall number of academic patents is around 56,000 which is 10% of all patents invented in France. Even before the Innovation Act, this share was 5.5%.

We find supportive evidence of a transitory learning phase after the Innovation Act. In the first six years post-reform, universities and PRO indeed increase the share of IPR retained and made important use of the co-ownership regime with companies. When distinguishing institutions with a previous IPR management experience (incumbents) from those without such experience (entrants), we observe that entrants are co-patenting even more and longer than incumbents. We interpret such evidence as a middle ground strategy allowing universities and PRO to comply with the new model while still in a learning phase.

The next section exposes the data collection. The following one portrays the academic patenting in France. Then, the third section pictures the evolution of the legal framework of universities and the recent trends in academic patenting while the fourth one investigates the shift in technology transfer strategies of universities. The last section concludes.

Data collection: Identifying academic inventions

An academic patent is a patent invented by at least one university researcher, independently of the type of applicant: it can be a university, a public research organization, the scientist herself, or a private company either exclusively; or jointly with other types.

Professors and researchers

In order to identify these patents, we need to determine which inventors are employed by universities. We have lists of professors and researchers associated with laboratories recognized by the Ministry of Higher Education and Research which contain, among other information, the first and last names, status (researcher or teacher-researcher), research and teaching fields, research unit, date of birth and gender. It is important to understand that all the French research system is organized in research laboratories (see Carayol & Matt, 2004). This covers in fact very different sorts of institutions, which size for instance can vary from a few professors and researchers to several hundreds. These data are compiled every four- to-five years. Each year approximately, a fourth of all labs in France provide such lists. As our lists have been constituted since year 2005 to year 2016, most labs in France have been surveyed this way at least twice. Some may have been surveyed only once because they have been created or have been terminated over the period. Another reason why a lab could have been surveyed only once is because the coverage of the data is increasing over the years so that some labs were not considered in the first years. As professors and researchers are likely to be listed several times (either in the same lab or by different labs if they moved for instance), a systematic disambiguation has been performed through various automatic and manual procedures. All in all, the data concern 61,223 faculty members, researchers and some engineers.

One important challenge of our work will be to identify whether the probability of those professors and researchers to invent is evolving over time. We therefore create a panel dataset.

Inventors

Patent data are extracted from the "EPO Worldwide Patent Statistical Database" (PATSTAT). We restrict the data to all inventors having a home address in France and having participated in the invention of a patent filed at the EPO, the USPTO or the INPI (French national office). That dataset does not contain any identification code for inventors. Therefore, a preliminary step is to define a reliable identifier for inventors. To do this, we use the algorithm proposed by Carayol, Cassi & Roux (2015). This algorithm basically relies on a Bayesian approach to compute similarity scores which are the probability that several identities correspond to the same person given a series of observables (i.e. the applicant, technological field, address, and backward citations to other patents). The algorithm uses a set of nearly five thousand verified (positive and negative) matches to benchmark itself. The error rate remains very limited (less than 2%).

Filtering academic patents

Once the inventor disambiguation step is completed, we use a statistical model to estimate the probability that all possible matches between academic researchers and professors on the one side and inventors on the other side are correct.

This is in fact a three-stage procedure. In a first stage, we estimate a logit model on a set of validated and unvalidated couples. This benchmark was constituted on the basis of experts (mainly professionals of technology transfer employed in universities) identifying professors as potential inventors. The benchmark is constituted of nearly seven hundred professor-inventor pairs having similar family names. We found out that regressions per office are more efficient. As explaining variables, we include the Jaccard similarity between family names, the inventor name frequency (in log), the distance between the patent technological classification and the professors' scientific disciplines as defined by Magerman, Callaert & Van Looy (2017) (in log), as well as weighted dummies signaling consistency between the professor age and the patent application year and between the assignee name and the professor employing institution. The regressions are performed by office as a Hausman test shows logit coefficients are significantly different across offices. The regression results for each office are presented in Table 1.

Table 1: Logistic regressions on the benchmark, per office.

	EP	EP	FR	US	US	US	US
name similarity	22.43***	21.83***	12.74***	38.79*	38.10***	39.11***	38.02***
inventor's name frequency	1.23***	1.24***	0.64***	1.65**	1.68***	1.68***	1.71***
assignee/employer consistency	6.24***	6.23***	1.27***				
tech/discipline consistency	0.57**	0.59***	0.43**	0.64	0.72		
age/year consistency	0.67		1.25***	-2.57		-2.65	
intercept	-32.19***	-29.19***	-21.84***	-38.77*	-47.58***	-38.62**	-47.23***
N	682	682	2829	115	115	115	115

The second step uses the estimated coefficients to predict the probability that potential matches are correct or incorrect on the whole reference population.

In the third step, we consider various thresholds of the probability for accepting of rejecting matches that we note p.

Let $TP(p)$ denote the number of true positives in the benchmark for a given threshold probability value p, $FP(p)$ is the number of false positives, and $FN(p)$ the number of false negatives. We can then compute the standard precision indicator: $P(p) = \frac{TP(p)}{FP(p)+TP(p)}$, as well as the recall indicator $R(p) = \frac{TP(p)}{TP(p)+FN(p)}$. As precision and recall vary in opposite directions with the threshold p value, we compute a synthetic indicator that takes both into account:

$$F_{\beta}(p) = (1 + \beta^2) \times \frac{P(p)\times R(p)}{\beta^2 \times P(p)+R(p)}, \quad (1)$$

with $\beta > 0$. In that expression, the parameter β weights precision and recall. If $\beta < 1$, precision is more weighted than recall, and the reverse holds when $\beta > 1$. As we would like our results to not be sensitive to a particular value of β, all our statistics will be computed for $\beta = 0.5, \beta = 1$ and $\beta = 2$.

We display, in Figure 1 the computed values of those indicators for the different threshold probability values p.

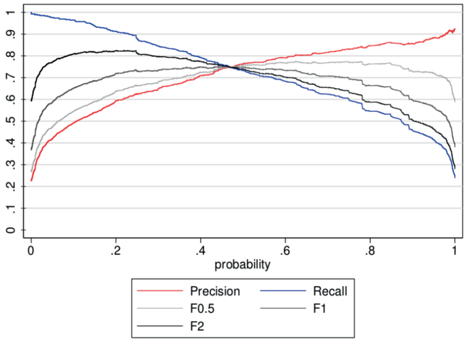

Figure 1: Precision, recall et F_{β} (when $\beta = 0.5$, $\beta = 1$ or $\beta = 2$) for different threshold probability values.

Our goal is to find and "optimal" p value, for a given β and patent office i. That is, we want to find: $p^*_{\beta,i} = argmax_p\{F_{\beta,i}(p)\}$, for each office i, with $F_{\beta,i}(p)$ the indicator defined in Equation 1, calculated on the patents of office i only. Given that we consider three offices and the F-measure is computed for three different values of β, we end out with a series of 9 = 3×3 thresholds. Optimal thresholds are sensibly different for each considered office (See Table 2).

Table 2: Optimal thresholds for each office and different β values.

office	Threshold	F-measure
EPO	$p^*_2 = 0.14$	$F_2 = 0.82$
	$p^*_1 = 0.44$	$F_1 = 0.77$
	$p^*_{0.5} = 0.46$	$F_{0.5} = 0.82$
INPI	$p^*_2 = 0.20$	$F_2 = 0.78$
	$p^*_1 = 0.45$	$F_1 = 0.69$
	$p^*_{0.5} = 0.74$	$F_{0.5} = 0.71$
USPTO	$p^*_2 = 0.24$	$F_2 = 0.86$
	$p^*_1 = 0.24$	$F_1 = 0.71$
	$p^*_{0.5} = 0.24$	$F_{0.5} = 0.60$

Calculating the "expected" number of academic patents

Let $N^1_{\beta,i}$ be the set of patents that are validated in office i and for a probability threshold $p^1_{\beta,i}$. The cardinal of that set is $n^1_{\beta,i}$ and $n^0_{\beta,i}$ is the number of non-validated patents.

The patents in $N^1_{\beta,i}$ are the validated ones for some criterion captured by β. As such those patents are the one that we will keep as our set of academic patents on which we will calculate many things. But assuming that $n^1_{\beta,i}$ reflects the expected number of academic patents would be slightly misleading. Indeed, patents counted in the underlying set have been misreported as such (false positives) while patents in the complement are also misallocated (false negatives). The expected number of patents can be calculated as follows:

$$\hat{x}_\beta = \sum_i \left[\frac{TP(p^*_{\beta,i})}{FP(p^*_{\beta,i})+TP(p^*_{\beta,i})} \times n^1_{\beta,i} + \frac{FN(p^*_{\beta,i})}{FN(p^*_{\beta,i})+TN(p^*_{\beta,i})} \times n^0_{\beta,i}\right],$$

for a given threshold $p^*_{\beta,i}$ for each office i ∈ {EPO, INPI, USPTO}.

The different modes of calculation provide very similar numbers as the estimated number of patents invented by our population of professors goes from 25,624 to 26,503. Moreover, 4.6% of French-invented patents originate from Academia. For the period 1995-2001 and only patents filed at the EPO, Lissoni et al. (2008) provide a lower estimation with 3,4% of the 48973 French-invented being academic. For the same period, we obtain a comparable number of patents invented in France, but a greater share (6%) of academic ones.

Table 3: Expected number of academic patents for several β values (from 1995 to 2012).

Office	$\hat{x}_2$		$\hat{x}_1$		$\hat{x}_{0.5}$		All French-invented patents
EPO	11072	(6.1%)	12320	(6.9%)	12325	(7%)	177286
INPI	11173	(4.5%)	10804	(4.3%)	10473	(4.1%)	250605
USPTO	3379	(2.5%)	3379	(2.5%)	3379	(2.5%)	134315
Total	25624	(4.5%)	26502	(4.6%)	26177	(4.6%)	562206

Academic patenting in France

The starting point of our methodology to collect all academic patents is the list of professors and researchers in France. However, the survey started in 2005 (until 2016) and covers only universities and PROs recognized by the French Ministry of Higher Education and Research (MHER). Hence, we know as a fact that we miss all patents invented by professors and researchers that were no longer active in 2006 or belong to a university or PRO not recognized by the MHER. We recover some of these missing academic patents by adding all patents that did not match on inventor's name but are owned by at least one French university or PRO to our academic patents pool. This leads us to Table 4, according to which at least 10% of all inventions in France between 1995 and 2012 come from Academia, and this is a floor value as academic patents owned exclusively by the private sector remain missing for the reasons mentioned above.

Table 4: Expected number of academic patents for several β values (from 1995 to 2012) – Alternative method.

Office	$\hat{x}'_2$		$\hat{x}'_1$		$\hat{x}'_{0.5}$		All French-invented patents
EPO	19786	(11.1%)	21034	(11.8%)	21039	(11.8%)	177286
INPI	24973	(10%)	24604	(9.8%)	24273	(9.6%)	250605
USPTO	10963	(8.1%)	10963	(8.1%)	10963	(8.1%)	134315
Total	55722	(9.8%)	56600	(10.1%)	56275	(10%)	562206

One of the motivation for the policy reforms introduced in Europe in order to converge to the Anglo-Saxon model was the common belief that European countries were lagging the US in terms of technology transfer. According to Lissoni (2012), the inventions made in universities and research institutions in the USA between 1994 and 2002 represented 6% of all US-invented patents. In Italy, the Netherlands and Sweden this share is 4%, 4.3% and 6.2% respectively.

The importance of academic patenting is France is estimated at 3.4%, which we can reevaluate with our data at rather 8%. Hence, the underperformance of France in terms of academic patenting appears unverified. Even before the introduction of the Innovation Act in 1999, France was doing at least as well as any other advanced economy.

We breakdown inventions by technological field. In Table 5, the first column of percentages indicates the repartition of academic patents across technological fields, while the second column of percentages point out the weight of academic patents among all inventions in the specific technological field. The leading fields in Academia are Chemistry (42.7%), followed by Electrical Engineering and Instruments (20.6% and 20.2% respectively), these shares being higher than in the overall distribution of patents for Chemistry and Instruments (30.2% and 12.8% respectively for all French-invented patents). Moreover, in the Instruments field, academic patents account for 15.1% of all patents, and in Chemistry 13.6%. While Mechanical Engineering is the second most important technological sector at the national level, academic inventions are clearly underrepresented in this field.

Table 5: Distribution of academic patents across technological fields for several β values (from 1995 to 2012).

Technological sector	Academic patents only ($\hat{x}'_1$)			All French-invented patents	
Chemistry	35549	(42.7%)	(13.6%)	259599	(30.2%)
Electrical Engineering	17175	(20.6%)	(9%)	191244	(22.2%)
Instruments	16805	(20.2%)	(15.1%)	110607	(12.8%)
Mechanical Engineering	11082	(13.3%)	(4.9%)	224255	(26.2%)
Other fields	2699	(3.2%)	(3.7%)	70176	(8.1%)
Total	83309	(100%)	(9.6%)	855881	(100%)

Finally, Table 6 provides the participation level of professors and researchers to the academic invention phenomenon by scientific discipline (for medical and hard sciences only). Overall, one professor over five has filed at least one patent between 1995 and 2012. In line with the previous findings, professors in Chemistry are particularly involved, with 32.5% of them being academic inventors. In all other disciplines the share of professors that are also inventors is very homogeneous at approximately 22%, except for Universe Science (12.5%).

Table 6: Repartition of professors and researchers involved in academic patenting by scientific discipline (1995 – 2012)

Scientific field	professors-inventors		All professors
Chemistry	2485	(32.5%)	7653
Applied Bio. Ecology	2119	(22.3%)	9497
Fundamental Biology	3426	(23%)	14890
Medicine	3315	(24.3%)	13624
Engineering Sciences	2806	(24%)	11714
Math	1601	(20.9%)	7674
Physics	2186	(24.4%)	8965
Universe Science	453	(12.48%)	3630
Total	8367	(21.4%)	39069

Notes:

– 23670 professors and researchers in Human and Social Sciences are not represented in this table. 1101 of them have invented at least one patent over the period, but 300 are already accounted for in one the other engineering and hard sciences disciplines. The net share of inventors in Human and Social Sciences is 3.4%. If these SHS inventors are included in the full sample (61223 researchers), the global share of academic inventors goes down to 15.2%.

Science policy and recent trends in technology transfer in France

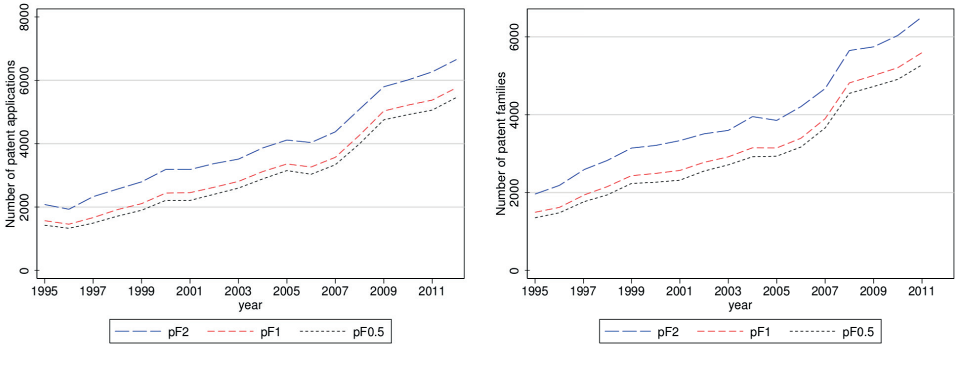
Science policy and technology transfer

Before exposing the recent evolution of technology transfer in France, we need to first depict the numerous policy initiatives affecting technology transfer introduced in the last fifteen years. In France, universities and PROs had the rights over the research of their professors and researchers and thus a legislation equivalent to the Bayh-Dole Act was not necessary. However, these institutions did not manage this function historically. Therefore, national policy aiming at encouraging technology transfer essentially consisted in sustaining the development of technology transfer in these public institutions.

The most important piece of policy is the 1999 law on Innovation and Research (Loi Allègre) allowing universities to create internal services for managing contracts and transfer (SAIC). It created a series of public incubators. The law also modified the status of professors and researchers (who are civil servants in France), favoring mobility to (temporary) positions offered by companies, allowing professors to perform consulting activity for companies (to a certain extent), and take equity positions in start-ups capital.

In 2005, the Agence Nationale de la Recherche (ANR) has been created to implement project-based funding in France. Therefore it funds numerous collaborative research projects between companies and academic labs. That law also created the Instituts Carnot (somehow designed under the Fraunhofer Institutes model) which were created to support collaborative research with companies. In 2010, a very large financial plan called "Programme des Investissements d'Avenir" (PIA) was launched to sustain the emergence of strong research players (laboratories and university sites) in the French research system. It supported the creation of 14 SATTs ("Sociétés d'Accélération de Transfert de Technologie"). The goal was to increase the professionalization of transfer and to favor other economies of scale, in particular in research universities, by increasing their budget thanks to substantial subsidizes (more than 0.8 billion euros altogether).

The left graph of Figure 2 shows that the number of academic inventions has dramatically increased in France over the last two decades. The right graph concerns patent families. That variation corresponds to an increase by a factor 3.



Note: the year of family applications are earlier or equal to the year of applications. Hence, we have consistent estimations until 2011 for families and until 2012 for applications.

Figure 2: The evolution of academic patenting in France: number of patent applications in the three offices (left graph) and number of patent families (right graph).

Policy and different actors' behaviors

Propensity calculation

The above calculations may be misleading as in fact the underlying population of professors and researchers that we consider is likely to be increasing over the period. Indeed, our population identification corresponds to years 2005-2016. Most of them are likely to be active for those years, but less in the preceding subperiods. Therefore, we should now calculate which of those professors and researchers are to be considered each year and exclude all the inventions attached to them outside these individualized ranges of time. This leads to Figure 3. The number of patents is larger than in the previous figure, we now consider inventions in patents, and those co-invented by several of our professors and researchers are counted several times. We can see in this Figure 3 that the number of professors and researchers is increasing very rapidly as well, at a slope which is comparable or slightly higher than the one of their patents. Therefore, it seems that the propensity to invent (expected number of patents per year per capita) remains pretty stable over the considered period.

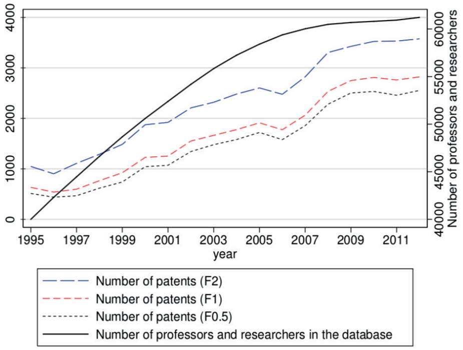


Figure 3: The evolution of academic patenting in France, with respect to the reference population.

More generally, it is then likely that other variables may affect the probability to invent over time. As these factors are not controlled for in the previous simple analysis, our estimates may end out being biased. We run negative binomial regressions (as the dependent variable is a count variable, which is overdispersed), to estimate the probability to invent each calendar year controlling for confounding factors such as age, age squared, academic position and university of affiliation and it appears that the introduction of such control variables only marginally reduces the coefficient associated with the years.

Furthermore, there exists a natural propensity to invent outside of Academia. Our strategy is then to deduce from the academic propensities to invent the natural (or non-academic) ones in order to observe a potential effect of public policies on the propensity to invent in Academia every year. The following regressions will not include anymore the control variables as we do not have personal information for the non-academic inventors. Thus, we run negative binomial regressions to estimate the probability to invent each calendar year. The incidence rate ratios of each year dummy on the number of academic patents (red curve) calculated with threshold F1($\hat{x}_1$) as well as the number of non-academic patents (blue curve) are synthesized in Figure 4. The propensity to invent in Academia is clearly departing from the one in the non-academic sector from 2006 ongoing (Figure 4). The largest year dummy incidence observed is for year 2010 which is up to 3.5 times more than 1995, or 2.5 when deducing the natural propensity to invent. At this point, we cannot say with certainty whether it is specifically due to the Innovation Act of 1999 or to the creation of the ANR, the national institution dedicated to project funding on a nation-wide basis, or even of the Instituts Carnot favoring the technology transfer, or a combination of all these public policy implementations. However, it appears clearly that the public policy in its globality triggered the post 2007 increase in propensity to invent in academia.

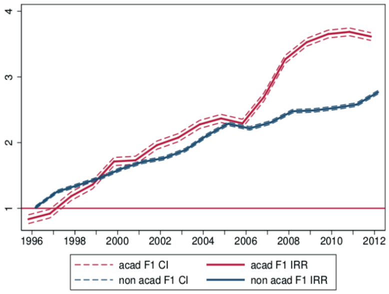

Figure 4: How the propensity for invent is affected over the years for non-academic (left panel) and academic (right panel) inventions (dependent variable xˆt1).

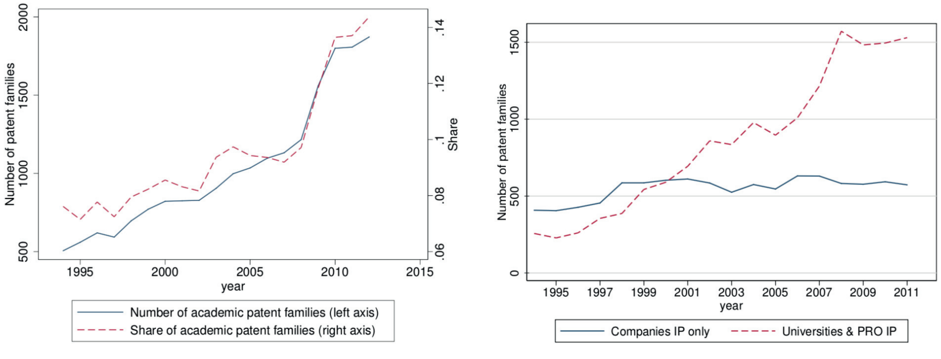
The adjustment of technology transfer strategies

If policies affected the propensity to invent, they may also have affected the propensity to assign the rights of those patents to universities. We investigate now how the propensities to invent vary according to the type of assignees.

We have extracted all patents (from the same offices as before) and identified which ones are owned by universities, government labs and schools, it will be our universities and PROs category, and those owned by companies will be the category of the same name. The left graph of Figure 5 shows that academic institutions have taken an increasing part of patenting activity in France over the last 18-year period, from less than 8% to more than 14% of all patent families in 2012. That variation corresponds to an increase in the number of patent families by a factor 2.5. If we focus on the most recent period, we observe an impressive shift over the 2007-2010 period: the number of patent families owned by universities and PRO raised from less than 10% to nearly 14% of all patent families.



Note: In the left graph, the identification of university-owned (and PRO) patent families (in the EPO, INPI and USPTO) is based on the identification of at least one public player among the applicants (a university, school or PRO). We restrict to the patents one inventor of which at least is localized in France. The right panel is based on patent families invented by at least one of our professors and researchers, patent co-owned by universities and PRO and companies are included into the universities and PRO category.

Figure 5: The evolution of university owned and non-university owned patents in France.

Therefore, we have identified in the academic patents how they distribute according to their type of assignee. The yearly volume of patents owned by companies only remains very stable.

Meanwhile, the volume owned by universities and PRO exclusively or with companies has remarkably increased. If at this point it is difficult to attribute with certainty this evolution to one piece of policy or the other, this may indicate an effect of the policies rather on the ownership structure of academic patents than on the invention phenomenon itself.

We therefore make the same calculations as in the previous subsection, relying on a controlled population of professors and researchers over the years. Figure 6 shows our results. The academic patents owned by companies only remains very stable over the whole period while those owned by university only or in shared property between university or PRO and companies is in rapid growth. The universities seem to increasingly retain ownership over their inventions. Next, we run negative binomial regressions to estimate how the probability to invent varies over time, for each different type of assignee.

Figure 7 shows how the incidence ratio rates vary according to the year dummy, for each type of assignee. The propensities to invent are clearly following divergent paths. Even though the propensity to assign right to the business sector are higher from 1998 ongoing as compared to 1995, it remains particularly constant from then until 2012. As a comparison, the propensities are up to 6 times higher when it comes to assign rights to the universities and PRO only, and up to 20 times to co-assign rights between the business and universities and PRO sectors. This points out a change in the universities technology transfer strategies.

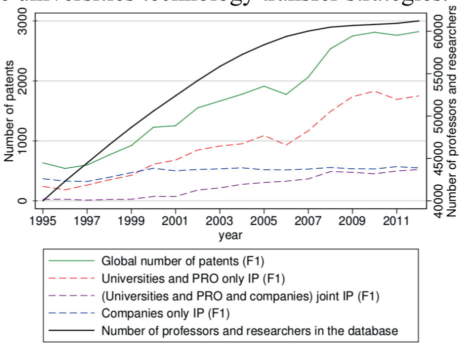


Figure 6: The evolution of academic patenting in France, with respect to the reference population.

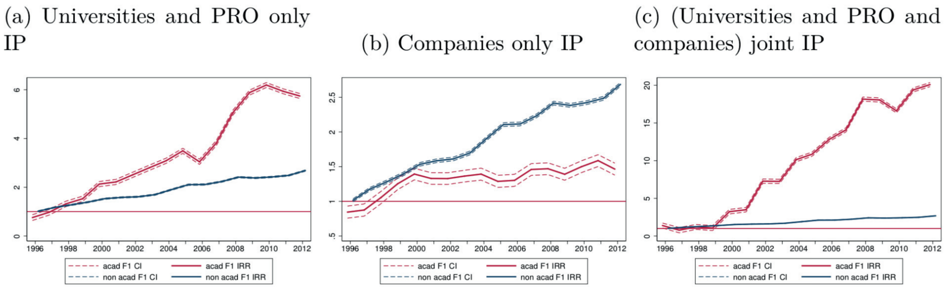
However, our database evidences a great heterogeneity in the practices of universities concerning the allocation of IPR. For example, while the University of Grenoble Alpes historically retained ownership of more than 80% of its inventions over the period 1995-2012, the University of Lorraine uses to wave more than 40% of its IPR to companies. Moreover, when most institutions increasingly retain the ownership, some did not change their TT strategy. Public research organizations such as CNRS, CEA and INSERM waive their property rights for a small share of patents only (usually between 20% and 30%) whereas the main universities usually leave between 40% and 60% of their patents. Increasingly, patents are co-owned by universities (and PROs) and companies, as proved by some large universities such as Lyon 1, Bordeaux 1, or Rennes 1 which share the property of a quarter to a third of their patents. If we focus more specifically on the five main universities (Aix-Marseille, Paris 11, Paris 6, Grenoble 1 and Lyon 1), we notice that Grenoble 1 keeps the full property of 53% of its inventions, while Aix-Marseille abandons almost the same share to companies and Lyon 1 co-owns 29%.



(a) Universities and PRO only IP

(b) Companies only IP

(c) (Universities and PRO and companies) joint IP

Figure 7: How the propensity for invent a patent for different types of IP owners is affected over the years (dependent variable $\hat{x}_t^1$ per type).

As evidenced previously, we observe a progressive shift in technology transfer strategies of universities and PROs in France. Indeed, these public entities are increasingly retaining property over their inventions. Companies lose the full ownership of academic inventions to the benefit of co-ownership with the universities and PROs until 2006, and then to the universities and PROs full property.

A one size-fits all reform may be inappropriate as regard to the diversity of the French institutional landscape in terms of IPR management experience. More than 50% of universities and PRO never applied for a patent during the 18 years under study. During the pre-reform period (1995-1999), 72 institutions applied for 2 patents or less (the entrants) and 17 institutions filed 10 patents of more (the incumbents). This last group includes the universities Paris 7, Strasbourg, Montpellier, Grenoble Alpes and Paris 6 and they applied for 51 to 88 patents in the 5 pre-reform years. Finally, the level of experience of 28 institutions which applied for 3 to 9 patents is unclear so we exclude them from the sample. For each group separately, we compute the growth rate of their share of patents co-owned with companies (Figure 8). It appears clearly that universities without pre-reform IP management experience used the co-ownership regime 6 times more often in 2000-2002 as compared to 1997-1999. They used it more and longer than incumbents.

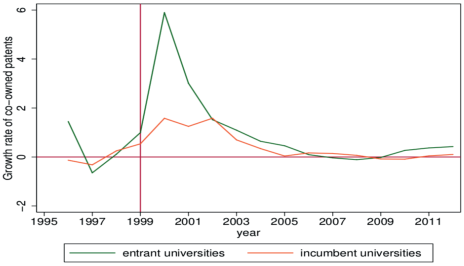


Figure 8: The growth rate of co-ownership share by entrants vs. incumbents.

Conclusion

After the implementation of the Bayh-Dole Act in the 80's in the USA, numerous studies followed in order to assess the real impact of this law and its efficiency (Mowery et al. (2001), Mowery et al. (2015), Mowery & Ziedonis (2002), Baldini, Grimaldi & Sobrero (2007) to mention just a few). In France, similar reforms since 1999 have been implemented in order to progressively reshape the research context of academic professors and researchers. However, still little is known on the impact of these policy initiatives on the universities technology transfer. First of all, our study aims at evaluating the amplitude of the academic patenting phenomenon in France over a large period. Next, we assess the impact of the different policies on the technology transfer strategies of universities and public research organizations.

According to our results, academic patenting represents up to 10% of all inventions in France over 1995-2012 (5.5% before the reform), that is more than 56,000 patents. Controlling for the evolution of the population and the confounding effect of different individual characteristics, we observe that the propensity to invent is increasing over time. After the Innovation Act was introduced, university professors and PRO researchers increasingly patented with a 6-year lag. Then, we explore the ownership structure. The share of patents owned by universities and PRO only or co-owned with a company is clearly increasing over time, while the share of patents owned by companies only remains constant. The universities are thus increasingly retaining ownership over their inventions. Looking at universities and PRO IP management strategies, we observe they adopted a transitory co-ownership strategy before starting to significantly apply on their own (in particular entrants), which we interpret as corresponding to a "learning phase".

The Diffusion of Zebrafish in Latin American Biomedical Research

A Study of Internationalisation Based on Bibliometric Dynamic Network Data

Rodrigo Liscovsky Barrera

rliscovs@ed.ac.uk

University of Edinburgh, Institute for the Study of Science, Technology and Innovation (ISSTI), Old Surgeon's Hall, High School Yards, Edinburgh (UK)

Abstract

Zebrafish (*Danio rerio*) has become an attractive experimental animal model in contemporary biomedical research. This study analyses the international dimension of the diffusion process of this popular model from a multi-level perspective by looking at the collaborative links forged by research institutions and the patterns of mobility displayed by individual researchers across time. To do so, first, it takes insights from diffusion of innovations theory and applies novel statistical techniques to measure network dynamic exposures using bibliometric data. Second, it builds on recent methodologies for developing scientific mobility indicators also based on bibliometric data. The analysis compares network diffusion patterns in selected countries with those displayed in Latin America. The growth of zebrafish research in this region is unprecedented and constitutes an interesting case to answer, from a new angle, long-standing questions on internationalisation dynamics put forward by STS scholars. Results show that a slow and progressive diffusion process has driven the use of zebrafish where high levels of network exposure (resorting to others with prior experience in the use of the model) play an important role. In the case of Latin America, however, expertise-based collaborations are not predominantly international yet international mobility is a common characteristic among early adopters.

Background: zebrafish research in Latin America

Although the use of zebrafish in biomedical research has been growing steadily on the world-stage after the successful completion of the first two large-scale random mutagenesis screens of zebrafish embryos in 1996 (see Nüsslein-Volhard, 2012), in Latin America this growth has been unprecedented (Buske, 2012). The promise of zebrafish in this region is mainly due to the economy of the model allowing average laboratories which often operate in national scientific systems shaped by budget constraints and with less well-developed science infrastructure, to conduct word class research (Allende et al, 2011). This has translated into a remarkable increase of publications from Latin American researchers, which has outpaced the growth of publications in other model organisms. Moreover, international collaboration seems to play a key role as expressed by the remarkable growth of internationally co-authored publications (see *figures 1a* and *1b*).

An important source that contributed to the spread of zebrafish in the scientific community are stock centres. However, the formation of a regional stock centre, as those existing in the U.S., Europe and China (Friedmann et al, 2015), was considered out reach for this region given the budgetary efforts this would have required (Allende et al, 2011: 31). Instead, in December 2010 a group of principal investigators from Argentina, Brazil, Chile and Uruguay decided to create the Latin American Zebrafish Network (LAZEN) with the aim of "enabling resource sharing, starting collaborative research, identify funding opportunities and to enhance training" (ibid: 31). In this sense, one of the central discussions of the regional meetings, which later included research groups from Colombia, Ecuador, Mexico and Peru, revolved around how to disseminate and standardize regional zebrafish work. This has proven to be especially useful because the region is characterised by a lack of access to commercial holding systems and many of the researchers are self-taught in the art of fish husbandry (ibid: 33).

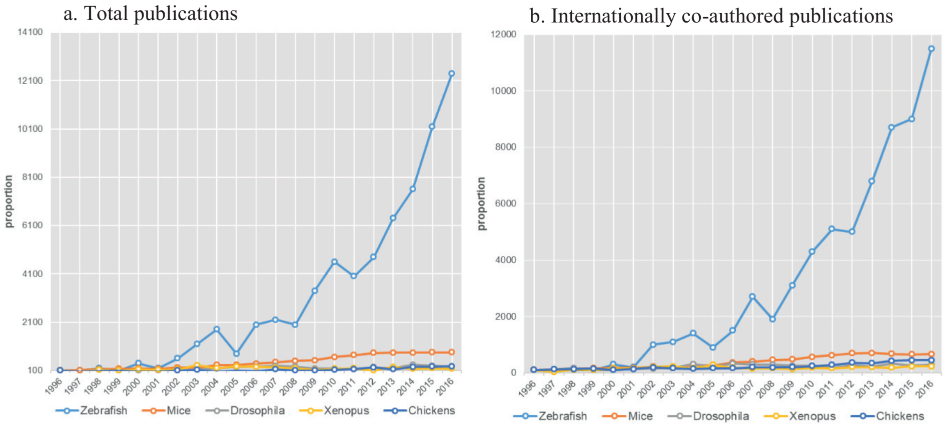

Figure 1. Evolution of publications in Latin America by type of model organism.
1996 = base 100. Source: CWTS Scopus XML internal database. Oct. 2018.

The reasons for the growing use of zebrafish in biomedical research are manifold including high genetic homology to humans, being a sufficient physiological complex in-vivo model that reproduces quickly and abundantly, having an external and transparent development, the fact that it is space/cost-efficient and ease for experimental manipulation among other factors (Kalueff et al, 2014a; 2014b). In most cases, the choice for this model organism is said to vary according to the research questions. In this sense, zebrafish is considered an effective third-path between simple multicellular organisms and complex and expensive vertebrate models such as mice and rats (Bateson Centre, 2014).

However, are scientific and practical factors the only factors that explain the rapid diffusion of zebrafish as an attractive novel organism in biomedical research? Do social factors including interpersonal links, shared expertise and mobility patterns influence this growth as well? How do these factors help explain the introduction of the model in Latin American biomedical research?

Science studies focused on Latin America have noted the prevalence of centre-periphery dynamics to explain how researchers from the region are incorporated and contribute to the global production and circulation of knowledge. Adopting insights from dependency theory and world-system approach, some scholars have noted how internationalisation played a key role in key disciplines such as biomedicine in determining the orientation of local research agendas (Kreimer 2006). In this sense, the personal relationships that local scientists forged with research leaders from central countries often characterised by a ‘subordinated integration’ where the latter retain a ‘cognitive control’ of local research (Kreimer, 2013: 443) via the exportation of techniques and research choices. Internationalisation and network dynamics are thus key elements to examine in the diffusion of zebrafish as a model organism in Latin American biomedical research.

Approach: diffusion theory, dynamic networks and international mobility

This study relies, on the one hand, on contributions from diffusion of innovations theory. Having its roots in anthropology, economics, sociology and other disciplines, diffusion theory seeks to explain how new ideas and practices spread within and between communities (Valente, 2010). The premise, confirmed by empirical research, is that new ideas and practices spread through interpersonal links (Ibid). Hence, social factors rather than economic ones are key factors influencing adoption behaviour (Valente and Rogers 1995; Valente, 2010).

The emphasis of the role of interpersonal links implies adopting a social network approach to study diffusion processes. Diffusion network studies provide useful empirical data for measuring network influences on diffusion (Valente, 2010). However, most of these studies are based on static networks (Valente, 2015) and fail to consider the dynamic nature of diffusion processes. Therefore, in order to study dependency dynamics, this study is based on previous dynamic network studies which investigate how exposure to prior adopters is related with adoption (Valente, 1995; 2005; 2015).

Second, this paper considers the key role that scientific mobility plays in knowledge diffusion and exchange processes (Robinson-Garcia et al, 2018). The study of scientific mobility is closely related to the study of internationalisation dynamics where researcher's international trajectories together with international collaboration proved to be highly correlated as measures of international engagement (Wagner & Jonkers, 2017: 32).

Data

Database 1: diffusion through collaboration

The data was retrieved in October 2018 from CWTS' Scopus custom XML database, which covers publications from 1996 onwards. In order to select publications on zebrafish in biomedical research, a SQL query was designed that used zebrafish's descriptors as defined in the Medical Subject Headings (MeSH) developed by the NIH. MeSH provides hierarchically-organised terminology for indexing and cataloguing of biomedical information such as MEDLINE/PubMed. The designed query parameters helped searching for zebrafish's MeSH descriptors[1] in the abstracts of publications that resulted in an initial sample of 28,973 papers published from 1996 to 2016.

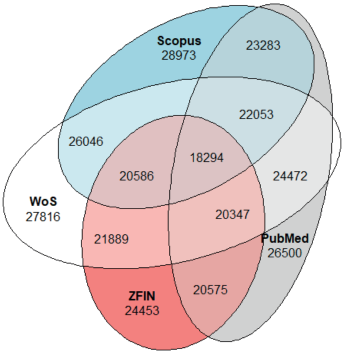

Figure 2. Venn Diagram of SQL query results depicting unique and overlapping publications identified in each bibliometric database.

To validate the representativeness of collected papers (that is, papers reflecting the use of the model in biomedical research) a two-step process was followed. First, the same query was

[1] MeSH descriptors: *B. rerio, Brachydanio rerio, D. rerio, Danio rerio, Zebra Fish, Zebra Fishes, Zebra danio, Zebrafishes.* Source: MeSH Descriptor Data 2018.

replicated in alternative bibliometric databases including the Web of Science (WoS), PubMed and the online repository of publications developed by the Zebrafish Information Network (ZFIN) (see ***figure 2***). Publications overlaps across datasets were then analysed and the results showed that with WoS publications, there is a match of 49.4% whereas with ZFIN there is a 59.1% overlap. Overlaps with ZFIN are largely explained by the fact that the online repository includes a large number of PhD and master theses and non-peer-reviewed publications. A close inspection of journals in the WoS sample showed a variety of journals not belonging to the Life Sciences. However, with publications from PubMed there is match a 94.7% suggesting that a wide majority of retrieved articles are medical research articles. Second, to ensure retrieved publications refer to research that made explicit use of zebrafish as an experimental model (be that as the main model or as a complementary one), both the query and a small random sample of articles were reviewed and validated by an expert in biomedical research and zebrafish.

Sampling:

Unique research institutions were identified using their affiliation ID in Scopus. Furthermore, as the focus is set on the analysis of diffusion via collaborative links, papers with a large number of contributors were dismissed in order to select papers where institutions are thought to have made a substantial contribution. Papers with no more than 15 institutions were chosen by inspection of the distribution of the number of institutions per paper and the cumulative density function. This approach is consistent with previous studies (Deville et al, 2014; Martin et al, 2013). As seen in ***figure 3***, a deviation from the power-law fitting line is observed for those papers containing more than 15 institutions in the sample. Applying this filter results in a set of 28,624 unique publications, which means that only 1.20% of all collected papers are missing from the initial query.

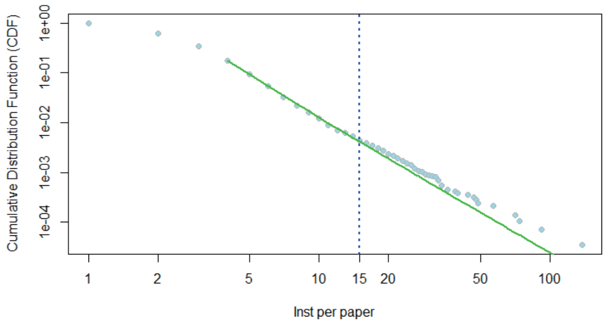

Figure 3. Cumulative Density Function of number of institutions per paper. The vertical line falls at 15 institutions corresponding roughly to the point where the distribution deviates from the power law

Data structuring:

'netdiffuseR' is an R package developed by Young et al (2018) that allows conducting empirical statistical analysis, visualization and simulation of diffusion and contagion processes on networks via so-called '*diffnet*' objects. These objects are lists that hold a series of other objects such as a graph, *toa* (an integer vector of size *n* that holds information about the time of adoption), a matrix of cumulative adopters and vertex's both static and dynamic attributes among other. To build a diffnet object, the package can read data in various formats including cross-sectional and longitudinal surveys as well as edge-lists. In this case, data was structured as a longitudinal co-authorship edge-list hence the resulting graph is dynamic and contains both static and dynamic attributes. To assure that institutions listed in the edge-list are institutions that used the model consistently, only those who published in more than one year were included in the sample. The application of this filter returns a sample of 3,771 unique institutions of which 124 are from LAZEN countries[2].

The *time of adoption* (toa) of each institution was computed by taking the year of first publication on zebrafish. Other attributes include country of affiliation (static), the size of the network at each time point (dynamic), the publication year (dynamic) and the number of collaborative countries at each time point (dynamic).

The resulting dynamic graph is composed of 7,220 nodes (including adopters and non-adopters) and 21 time points (1996 - 2016) recording 64,419 co-authorship events in total.

Database 2: mobility trajectories of zebrafish researchers

In order to analyse patterns of mobility among zebrafish researchers, an additional dataset was built comprising all the records of publications by individual authors included in the zebrafish dataset (database 1). Individual scientists were identified using their unique author ID in Scopus which combines all publication records from an author and his/her possible name variants. Recent studies have reported that the use of the Scopus author ID allows conducting precise and reliable analyses (Moed et al., 2013; Aman, 2017). The whole record of publications was also extracted from CWTS' Scopus custom XML database although in this case the constructed debased also includes publications that are not about zebrafish. In total, the mobility database contains 2,197,571 publication records.

Sampling:

Only authors that published more than once on zebrafish were selected. The application of this filter returned a total sample of 25,511 unique researchers which represents 31.49% of the total number of researchers included in the zebrafish dataset (n = 81,012). In addition, in order to identify authors from LAZEN countries, the previous cut-off parameter was further restricted to include only authors that published a minimum of two years under an affiliation from one of the countries that take part in the regional network. In total of 170 unique LAZEN authors were identified. The affiliations histories of each LAZEN author identified were then manually inspected in order to identify and exclude authors with multiple affiliations that do not necessarily reflect a Latin American researcher.

Data structuring:

To build the mobility dataset, institutional affiliation changes from each individual's history of publications were analysed following the classification developed by Robinson-Garcia et al (2018), which distinguishes between migrants and travellers.

In a researcher mobility trajectory (see ***table 1***), '*Directionality*' indicates whether it is possible to reliably establish if an author has been chronologically affiliated first to his/her country of first affiliation and then to any other country, which is different from the country of origin. '*Rupture*' refers to a mobility of event where a researcher's country(ies) at t_n (t=0) are not found among the affiliations of the researcher at t_n+1 (Ibid).

[2] Argentina, Brazil, Chile, Colombia, Ecuador, Mexico, Peru and Venezuela.

Table 1. Sample of a researcher's mobility trajectory. Directionality implies a researcher gains additional affiliations while maintaining affiliation with his/her country of origin.

Au-id	*pub year*	*country*	*t*	*event type*	*mobility class*
60001812493	2003	Argentina	0	Origin	Migrant
60001812493	2007	Argentina	4	Origin	Migrant
60001812493	2007	United Kingdom	4	Directionality	Migrant
60001812493	2007	Argentina	4	Origin	Migrant
60001812493	2008	United Kingdom	5	Rupture	Migrant
60001812493	2009	United Kingdom	6	Rupture	Migrant
60001812493	2010	United Kingdom	7	Rupture	Migrant
60001812493	2011	United Kingdom	8	Rupture	Migrant
60001812493	2012	Argentina	9	Origin	Migrant

Consequently, researchers can be classified as:

- *Migrant*, if they display a directional mobility event and a point of rupture with their country of origin (t=0) at any point in time;
- *Directional Travellers*, if they display a directionality event but no rupture throughout their publication history;
- *Non-Directional Travellers*, if they have at least one mobility event but no directionality and no rupture with their country of origin.
- *Not mobile*, if they lack any mobility event (Ibid).

The resulting database contains 214,905 mobility events expanding from 1996 to 2016. Furthermore, mobility events for the 170 Latin American researchers identified were further classified as:

- *LAZEN Origin*, if researchers' country of origin belongs to any of the LAZEN countries;
- *International Origin*, if researchers' country of origin is different from any of the LAZEN countries;
- *International Migrant*, if they have had a rupture event at a country that is not from the LAZEN region;
- *LAZEN Migrant*, if they have had a rupture event at any of the LAZEN countries;
- *International Directionality*, if they added affiliations from countries outside the LAZEN region;
- *LAZEN Directionality*, if they added affiliations from any of the LAZEN countries.

Methods:

Diffusion through collaboration

Adoption of an innovation does not occur immediately and automatically. Rather, adoption is a process that involves different stages such as becoming aware of the innovation, learning more about it, trying it and eventually adopting it (Valente, 2005). To observe this process, we can examine the evolution of the number of (cumulative) adopters across time. Trends of adoption can be further compared between communities of adopters – in our case, research institutions from different countries. The adoption process for Latin American research institutions is therefore compared with those observed in the U.S., the U.K, Germany and China, which are the main centres of scientific production on zebrafish.

However, despite its robustness, this measure – and other standard diffusion measures such as the *Rate of Adoption* or the *Hazard Rate*[3] – do not help explain dynamics at the individual level and at each point in time for the duration of the diffusion process. Fortunately, more dynamic models have been developed which treat time more explicitly and measure how an actor's social network influences the adoption and diffusion of innovations across time. To do this, these models – and diffusion research in general – rely on a key measure referred as *network exposure* (Valente, 2005). Network exposure is measured with the following equation:

$$E_t = (S_t \text{ X } [x_t \text{ o } A_t])$$

Where S_t is the network in time *t*, x_t is an attribute vector of size *n* at time *t*, A_t is the t-th column of the cumulative adopters matrix (a vector of length *n* with a_{ti} = 1if *i* has adopted at or prior to *t*), *o* is the kronecker product (element-wise), and X is the matrix product (Young et al, 2018). This means that for each individual institution, we can analyse whether it has adopted zebrafish as an experimental research model and how many of its immediate collaborators (co-authors) have adopted it at each point in time (outdegree), at or prior to ego's adoption. Moreover, thresholds levels can be calculated which are each vertexes' exposure at the *time of adoption* (toa).

In line with the previous measure, national and international exposure and threshold levels can be calculated for any given research institution in the social system. This is done by creating sub-graphs partitions of national collaborations and then calculating the proportion of collaborators who are adopters but from a country that is different to ego's country and then considering the whole size of ego's social network at each point in time. Therefore, *international network exposure* (E_i) is calculated as follows:

$$E_i = \frac{(E_o - E_n)}{Wi}$$

Where E_o is ego's simple exposure matrix at time *t*, E_n is on Ego's matrix exposure to national collaborators at time *t* (the network exposure matrix calculated from the sub-graph) and Wi is ego's social weight matrix at time *t*.

Considering this, we could expect a decrease in the effect of external expertise over time; a statement that is consistent with the general diffusion model, which argues that early adopters are influenced by sources external to the community (Valente, 2015: 90). That is, because there are no or few adopters in the community, early adopters tend to rely on information external to the community and, as diffusion develops, external dependency will tend to decrease and thresholds levels increase. Contrary to this, based on existing analyses on the influence of scientific internationalisation dynamics in Latin America, among early adopters of this region we should expect high levels international exposure and thresholds. In other words, Latin American research institutions will tend to rely on research institutions from central countries as expertise on the use of the model is expected to diffuse from the centre to the periphery.

[3] The Rate of Adoption is commonly referred as the relative speed in which actors adopt a given innovation (Rogers, 2003). The Hazard Rate refers to the instantaneous probability of adoption at each time representing the likelihood members will adopt at that time (Allison 1984).

Diffusion through mobility

The final part of the analysis is devoted to analyse the role of internationalisation in the diffusion process via bibliometric indicators of mobility. The interaction of researchers' mobility trajectories with their respective time of adoption (toa) is analysed. Mobility events and classes are computed for each researcher in the social system and grouped by distinct years of first adoption. This allows observing the extent to which an individual' mobility experiences have an influence on his or her timing for adoption. In addition, for each Latin American researcher, his/her geographical location at *toa* is recorded.

Taken together, these two methodologies provide a more dynamic and detailed account on the weight of internationalisation dynamics in the diffusion of zebrafish as a model organism in biomedical research.

Findings and discussion

Adoption process:

Instead of an exponential and rapid growth as documented elsewhere, a rather slow and progressive diffusion process has driven the use of zebrafish in biomedical research. As seen in ***figure 4***, the proportion of cumulative adopters (research institutions) increases gradually in all of the selected countries. In the case of China, this slow trend is even more noticeable although adoption among Chinese research institutions seems to accelerate from 2007 onwards. In both Latin America and China, however, adoption among research institutions displays a clear upward trend in the least years of the period of reference.

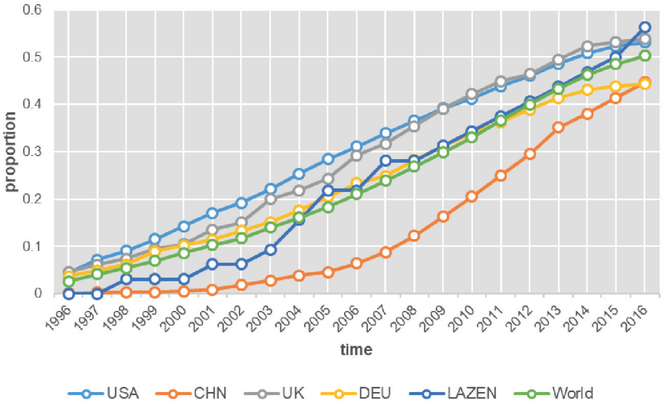

Figure 4. Evolution of cumulative Adopters Compared (%)

Network exposure and thresholds:

When looking at the network exposures at time of adoption (threshold) we can see that in both the global and Latin American communities, high network exposure levels are a common characteristic with a majority of adoptions taking place in the last years of the period of reference (***figure 5***). Particularly, research institutions in Latin America largely adopted zebrafish as an experimental model organism when a majority of their institutional collaborators (threshold >= 60%) had already adopted it.

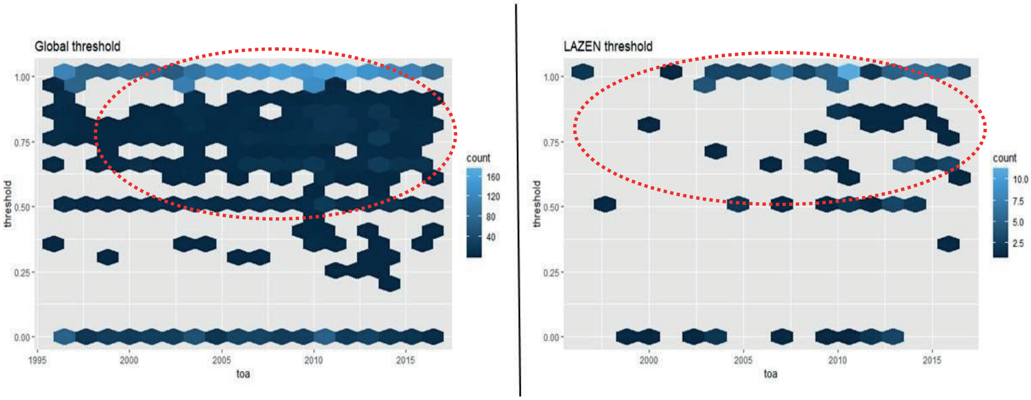

Figure 5. Research institutions' network exposure at adoption. Thresholds are each vertexes' exposure at the time of adoption (toa). *n* = 3,771 (global community) / *n* = 124 (LAZEN community)

This could indicate a prevalence of expert-based dependency dynamics in the adoption behaviour of Latin American research institutions but a closer look at the origin of such expertise reveals a different picture. As seen in ***figure 6***, expertise-based collaborations among Latin American research institutions are not predominantly international. The evolution of international exposures levels in the LAZEN countries shows that access to international expertise has been growing over the last years yet the average percentage of international collaborators with experience in using the model never exceed 30%.

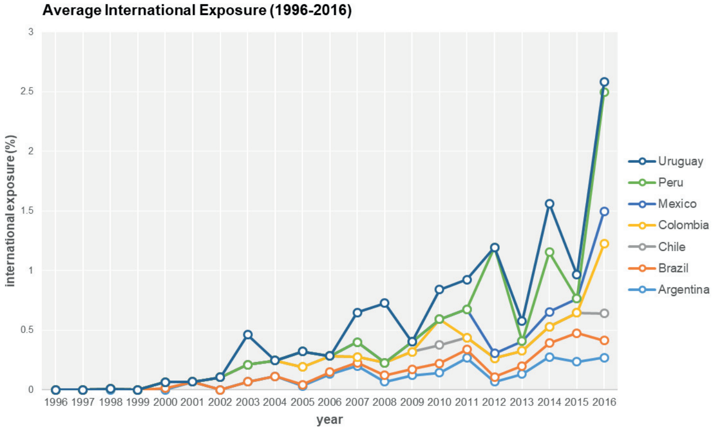

Figure 6. Evolution of average international network exposure levels among LAZEN research institutes (users).

Moreover, at *time of adoption* (toa), international exposure is even less determinant. When adopting the model for the first time, the large majority of Latin American institutions resort to national expertise or no external expertise at all. As seen in ***figure*** *7*, in most cases international threshold levels – resorting to foreign research institutions with experience in the use of the model – are equal or below 50%.

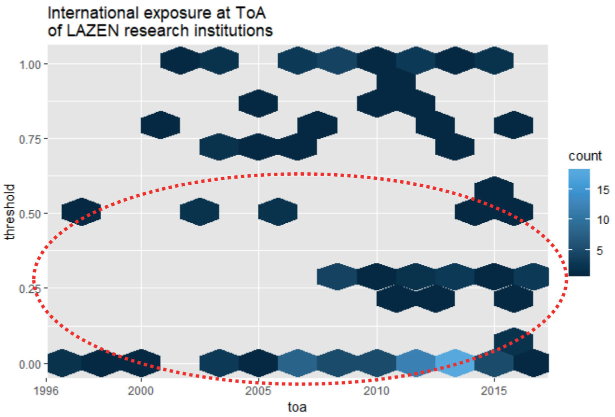

Figure 7. International network exposure at adoption for LAZEN institutions.
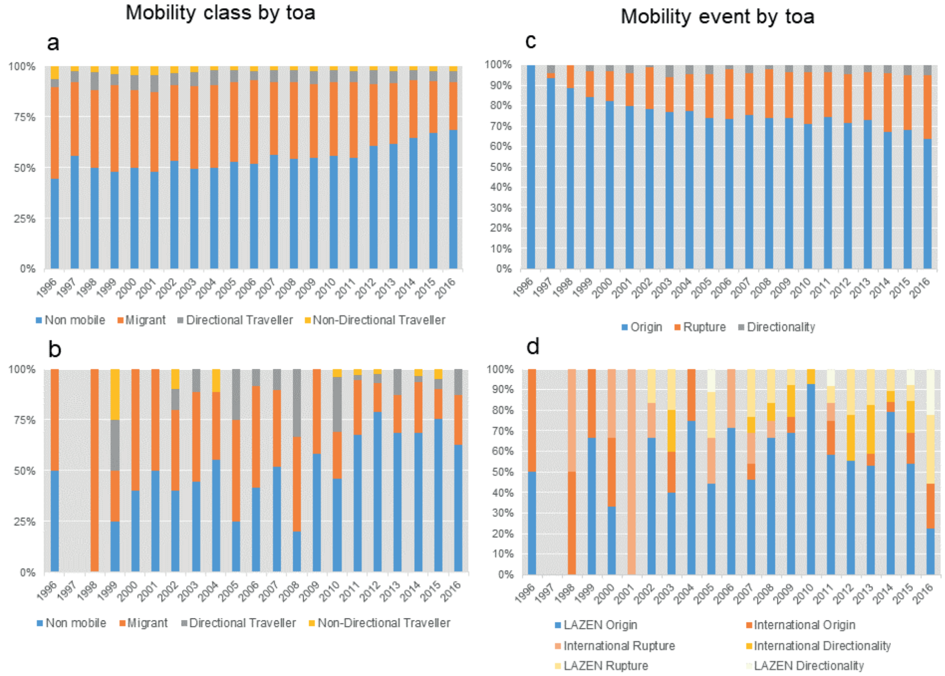
Thresholds are each vertexes' international network exposure at the time of adoption (toa).

International mobility
At the micro level, the distribution of international mobility patterns offers a more contrasting picture in terms of internationalisation dynamics (***figures 8a-d***). Among early Latin American adopters, the proportion of international mobile researchers – migrants, directional and non-directional travellers – (***figure 8b***) is substantially higher than that of non-mobile researchers, whereas in the global community the share of international mobile researchers has been decreasing over the years (***figure 8a***). This shows that international mobility is a key factor in the early adoption of the model, and this is especially true for Latin America researchers. The reduction of the share of Latin American mobile researchers from 2010 onwards, on the other hand, may suggest that returnees could have contributed to the diffusion of the model among local colleagues. However, the distribution of mobility classes does not consider the type of mobility event that took place at the time of adoption for each individual researcher. ***Figures 8c*** and ***8d*** provide a more detailed snapshot in this regard. In the global community of adopters, the large majority of adoptions (researchers' first publication on zebrafish) took place at their country of origin (***figure 8c***).

Among early Latin American researchers, however, adoption seems to have taken place when they were working abroad. Many early Latin American researchers either initiated their zebrafish research abroad (international origin) or started working with this model after travelling to another country (international rupture) (***figure 8d***) – mostly the U.S., the United Kingdom or Germany. In this sense, migration seems to be a common pattern among Latin American zebrafish pioneers. On the other hand, international directionality and regional mobility events (rupture or directionality) are more frequent among lagers although adoption at LAZEN countries becomes more prevalent over the last years of the period of reference – except for 2016.



Figures 8a-d. International mobility trajectories by time of adoption. Figures 8a and 8c display mobility class and mobility events at *toa* for the global community of adopters. Figures 8b and 8d shows mobility class and mobility rupture events of the researchers from LAZEN countries.

Conclusions

Zebrafish has become an attractive model organism in biomedical research ever since the publication in 1996 of the results of the first two large screens for zebrafish mutants performed in Tübingen (Germany) and Boston (U.S.). Using bibliometric data, the present paper analysed the diffusion process of this particular model while paying special attention to the Latin American region where its growth has been unprecedented. Results show that a slow and progressive diffusion process has driven the use of zebrafish in the wider community of researchers where high levels of network exposure seemed to play an important role. However, in the case of Latin America, international-based expertise does not seem to have a crucial influence in the adoption of zebrafish as a model organism among research institutions. At the micro level, the influence of internationalisation dynamics is clearer. International mobility is a common pattern among Latin American zebrafish pioneers, whereas gaining additional country affiliations (either from countries from outside or within the region) is more frequent among lagers.

Overall, this paper presented a multi-level and more dynamic account on the weight of internationalisation dynamics in knowledge diffusion processes by combining network diffusion measures with international mobility indicators. In particular, the explicit treatment of time in the presented measures allowed developing a more nuanced analysis of internationalisation dynamics. At the meso level, this was done by observing how institutions' international co-authorship networks influence the adoption and diffusion of innovations across time. At the micro level, it relied on novel methodologies for measuring the movement of scientists and examined how proposed mobility taxonomies interact with the timing of adoption of zebrafish as experimental animal model in biomedical research.

Abstract

We assess the use and potential of Gold Open Access (OA) in Finland, Flanders (Belgium), Norway, and Poland by comparing data at the level of articles from full-coverage databases in each country. The inclusion of the journals in the Directory of Open Access Journals (DOAJ) is used as a reference to determine Gold Open Access. Gold OA is on the rise in all four countries and across fields, but some countries, especially Norway, and some fields have a substantially larger proportion of OA publications than others, with the overall share of Gold OA ranging from 5.7% to 17.3%. Especially in the SSH, a mixture of local and international journals can be found, many of which are not indexed in databases like Web of Science. As such, our results indicate that an overview of the state of Gold OA is preferably obtained by comparing DOAJ to a full-coverage database.

Introduction

Open Access (OA) to research has been one of the major topics of discussion in the area of scholarly communication for over a decade. Traditionally, a distinction is made between author self-archiving – Green OA – and publishing in an OA journal – Gold OA. A more refined model has been proposed by Martín-Martín et al. (2018). Using the terminology of these authors, we focus on *libre*, *immediate* and *permanent* access to the *accepted peer-reviewed* text of journal articles. For the sake of brevity, we will use the 'Gold OA' terminology.

The Directory of Open Access Journals (DOAJ) has emerged as one of the major sources of information on OA journals (Piwowar et al., 2018), although it does not cover all Gold OA (Björk, 2019). Basic requirements for inclusion in the DOAJ include immediate access (no embargo) to all content in the journal; having a registered ISSN; and displaying clear information on editor, editorial board, author guidelines, and article processing charges (APCs). In March 2014, DOAJ launched a new and more stringent set of criteria for inclusion (Van Noorden, 2014), leading to rejection of many journals that were previously included. In January 2019, the DOAJ covers 12,420 OA journals.

In this paper, we examine and compare to what extent researchers in four European countries/regions – Finland, Flanders (Belgium), Norway, and Poland – make use of journals that are in the DOAJ. These countries have been chosen because each maintains a full-coverage database (Sīle et al., 2018). also covers journals that are not indexed in international databases like Web of Science (WoS) as well as journals that do not register DOIs. This sets our study apart from most other studies, which rely on WoS or Scopus (Archambault et al., 2014; Bosman & Kramer, 2018; European Commission, 2019), and is especially relevant for the social sciences and humanities. As such, the study provides a complete picture of how widespread Gold OA is among peer-reviewed journal articles in these countries.

Data and methods

For each country, we take into account all peer-reviewed journal articles published between 2011 and 2017 by authors at the country's research institutions. However, the temporal and/or disciplinary scope of the Flemish and Polish data is smaller due to limitations of the data sources in these countries. Table 1 provides an overview.

The metadata of journal, conference and book publications from fourteen Finnish universities is stored in the VIRTA Publication Information Service for the period 2011-2017 (Pölönen, 2018). In case of scientific publications, it is indicated if they are peer-reviewed or not. For this study we selected peer-reviewed journal articles published in 2011-2017. For the year 2017, the data collection is not complete. Each publication is also assigned a cognitive field classification according to OECD Fields Of Science (FOS; OECD, 2015). Finnish universities' co-publications appear as duplicates, and they may have different field classification. We use deduplicated publication counts but one article can be counted in several fields. A small number of publications is assigned to category 'Other', and so can be counted toward the total for all fields but is excluded from the field-specific analyses.

Table 1. Overview of data per country

Country	Time period	Fields	Number of articles	Number of journals
Finland	2011-2017	All fields	169,231	15,434
Flanders	2011-2016	All fields	114,134	12,214
Norway	2011-2017	All fields	123,865	14,173
Poland	2013-2016	SSH	120,111	8,577

The Flemish PRFS (Engels & Guns, 2018) consists of multiple parameters, two of which count scientific publications in, respectively, the WoS and the VABB-SHW. The VABB-SHW is a database that was constructed to alleviate the shortcomings of WoS in covering the social sciences and humanities. We consider all journal articles published in 2011-2016 that are counted in the Flemish PRFS, both in WoS (n=81,936) and in VABB-SHW (n=12,635). The analysis at disciplinary level is carried out using a cognitive classification (Guns et al., 2018) based on OECD FOS; 4 publications that could not be assigned to a discipline were discarded.

Data for Norway are derived from the Norwegian Science Index (NSI), a subset of the Current Research Information System in Norway (Cristin), with complete coverage since 2011 of all peer-reviewed scientific and scholarly publications from most research organizations in the country. The bibliographic data in NSI represent books, journal articles, articles in edited volumes, and articles in peer-reviewed conference series (Sivertsen, 2016). Only journal articles are included in this study, and they are counted only once even if several institutions have contributed to them. Field classifications are mapped against OECD FOS.

The data from Poland are limited to the years 2013–2016 and to the social sciences and humanities (SSH). In these years, Polish SSH scholars published 120,111 articles (deduplicated at the national level). Disciplines or fields are assigned according to a qualification-based classification (typically based on the author's PhD). 9,147 co-authored articles involve authors from both social sciences and humanities and are assigned to both fields.

An overview of DOAJ-covered journals, obtained from the DOAJ website, is matched against each national database by comparing the ISSN(s) recorded per publication to the print and online ISSNs registered in DOAJ. Our analysis includes all journals in DOAJ, whether or not they have been accepted after March 2014. If a journal has only started providing OA content in a given year, only publications from that year or later are considered to be OA. In addition to a general overview, we also present the results for four broad fields: Natural sciences & technology, Medical & health sciences, Social sciences, and Humanities.

Results

The overall share of Gold OA articles varies considerably by country and by field, ranging from 5.7% (Social sciences, Flanders) to 17.3% (Medical & health sciences, Norway). In each of the four fields, Norway has the largest share of Gold OA articles (Figure 1). North- and West-European countries tend to exhibit similar publication patterns, while Eastern European countries sometimes behave somewhat differently (Kulczycki et al., 2018). This does not appear to carry over to Gold OA publishing, at least not in the SSH: the share of Flemish OA publications is lower in both social sciences and humanities than any of the other three countries. This suggests that national context and incentives may play an important role.

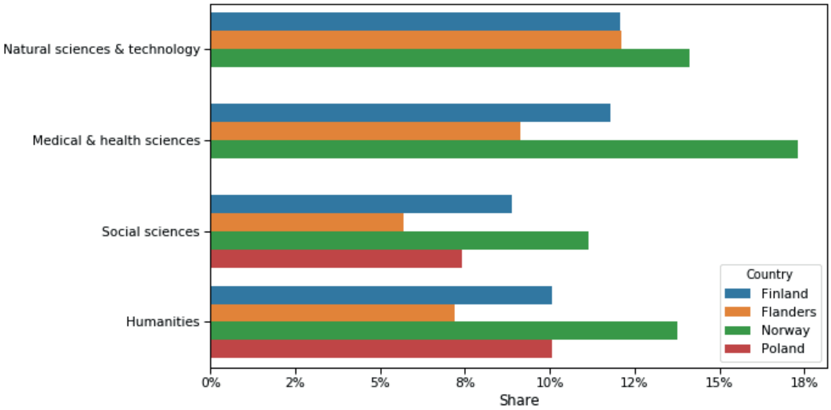

Figure 1. Share of Gold OA articles per field and country

The differences between countries and fields notwithstanding, the overall trend is clear: the share of Gold OA articles is linearly increasing (Figure 2). This increase may be due to multiple factors: the establishment of new Gold OA journals, changes to the business models of existing journals, and changes in journal choice of researchers. Figure 2 suggests that the ratios between the four countries are mostly stable, with Norway having the largest share of OA, followed by Finland and Poland, and finally by Flanders. The recent steep increase for Norway in the SSH is partly due to the establishment of a national OA platform for the most central journals published in the Norwegian language in SSH disciplines (Sivertsen, 2018).

Table 2 displays the 5 most used OA journals in Finland, Flanders and Norway. The top-5 tends to be dominated by international journals that are mostly multidisciplinary or from the natural sciences. Only the large multidisciplinary journals *PLOS One* and *Scientific reports*, as well as *Journal of High Energy Physics*, figure among the most used OA journals in all three countries. Because the Polish data is limited to the SSH, the Polish top-5 is completely different and does not contain any WoS-indexed journals.

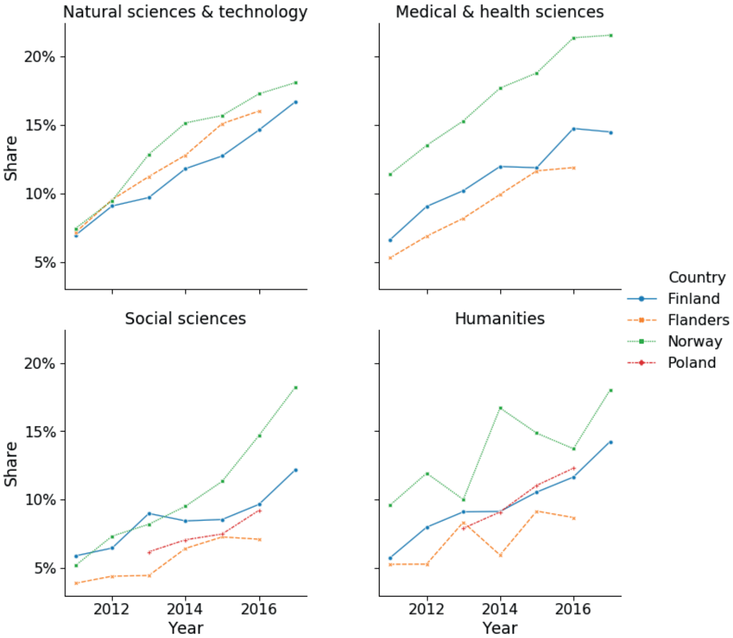

Figure 2. Evolution of share of Gold OA articles per field and country

Table 2. Top-5 most used OA journals per country

Finland	Flanders	Norway
PLoS ONE	PLoS ONE	PLos ONE
Scientific reports	Scientific Reports	Scientific Reports
Atmospheric chemistry and physics	Optics Express	BMC Public Health
Nature communications	Journal of High Energy Physics	BMJ open
PLoS genetics	BMC Public Health	Atmospheric chemistry and physics

For each of the four fields, we investigate one discipline in more detail: Biological sciences (Natural sciences & technology), Clinical medicine (Medical & health sciences), Educational sciences (Social sciences), and Languages and literature (Humanities). As can be seen from Table 3, the variability between disciplines and countries is, again, substantial. First, some disciplines are an order of magnitude larger than others in terms of number of articles. These size differences are not similar across countries, e.g., Educational sciences appears to be much larger (relatively speaking in terms of the number of articles) in Finland than in Flanders and Poland. Second, the share of OA publications of a discipline seems to be dependent on local circumstances.

Table 3. Number of publications and OA share per discipline and country

		Biological sciences	Clinical medicine	Educational sciences	Languages and literature
Finland	Total	12,375	32,291	4,086	2,656

	OA	2,075	3,088	583	275
	Share of OA	16.8%	9.6%	14.3%	10.4%
Flanders	Total	12,608	18,021	1,444	2,608
	OA	1,450	1,139	104	276
	Share of OA	11.5%	6.3%	7.2%	10.6%
Norway	Total	14,148	32,755	4,899	3,575
	OA	1,544	5,545	808	646
	Share of OA	10.9%	16.9%	16.5%	18.1%
Poland	Total	-	-	6,985	17,917
	OA	-	-	617	1,280
	Share of OA	-	-	8.8%	7.1%

We also investigate the most used OA journals per discipline per country. The distribution of papers per OA journal tends to be highly skewed, with the top-10 journals typically accounting for 50% or more of all OA publications in a given discipline. It is noteworthy that the two most important OA journals in Finland for both Biological and Medical & health sciences are the large multidisciplinary journals *PLoS ONE* and *Scientific reports*. Since disciplines in Flanders are currently assigned at the journal level, publications from either journal are treated as multidisciplinary, even if they may be about, e.g., biology.

Table 4. Number of non-English or multilingual journals among 10 most used OA journals

	Educational sciences	Languages and literature
Finland	4/10	6/10
Flanders	3/10	4/10
Norway	9/10	5/10
Poland	9/10	6/10

All top-10 journals for Biological sciences and Clinical medicine are English language, mostly published in the UK, US, Switzerland (Frontiers) and the Netherlands (Elsevier). Exceptions include Bulgaria (*ZooKeys*), Sweden (*Acta dermato-venereologica*), and Italy (*Haematologica*). The situation is rather different in the SSH, where we also find journals published in other languages (Table 4). These may target a local audience through use of the local language, but there are also examples of non-English journals that reach a broad international audience (e.g., *Zeitschrift fur interkulturellen Fremdsprachenunterricht* or *Teoría de la Educación*; cf. Sivertsen, 2018). In addition, there are several instances of multilingual journals, which accept articles written in two or more different languages. As for country of publication, we observe that in some cases the top-10 is largely international, albeit with greater geographical variation than for the natural and medical sciences (e.g., Educational sciences in Finland and Flanders). Other cases exhibit much more concentration in one or a few countries. In Poland, the ten most used journals of both SSH disciplines are all published in one of three Central and Eastern European countries (Poland, Lithuania, Ukraine), including the multilingual and English-language journals.

Discussion and conclusions

By comparing the contents of full-coverage databases to DOAJ, we are able to make an accurate assessment of the current state of Gold OA to peer-reviewed articles in four European countries. The same type of analysis can be used to monitor the further development towards Gold OA.

The overall share of Gold OA differs substantially between countries as well as between fields, and ranges from 5.7 to 17.3%. This finding suggests that the share of Gold OA depends not only on the number of possible OA publishing outlets in a given discipline, but also on more local and contextual factors, such as incentives and perceived quality level. Gold OA is on the rise in Finland, Flanders, Norway and Poland.

A closer investigation into four specific disciplines shows that the most important journals in Biological sciences and Clinical medicine tend to be English-language journals, mostly published by large international publishers. Note, however, that the results from Flanders for these two disciplines may be biased in favour of English-language journals, since the data for Natural sciences & technology and Medical & health sciences derive from WoS. In the SSH disciplines, we find both local and international journals. The latter group can be published in English or another international language, or in multiple languages. All in all, the results demonstrate that, especially for the SSH, the state of Gold OA can only be fully assessed by comparing to a full-coverage database.

Abstract

Methods of estimating the similarity between individual publications is an area of long-standing interest in the scientometrics community. Traditional methods have generally relied on references and other metadata, while text mining approaches based on title and abstract text have appeared more frequently in recent years. In principle, Topic Models have great potential in this domain. But in practice, they are often difficult to successfully employ and, in particular, are notoriously inconsistent as latent space dimension grows. That is, running the same model, with the same parameters, on the same data, but with a different random seed produces radically different similarity estimates as the number of topics increase. In this manuscript we develop a simple, but novel, methodology for evaluating the robustness of topic models. Employing that methodology, we find that the neural network based Doc2Vec approach seems capable of providing (statistically) robust estimates of document-document similarities, even for topic spaces far larger than prudent for the most common topic model approach: Latent Dirichlet Allocation. As this is a work in progress, we do not venture deeply into the question of whether these estimates also reflect reality, but do provide some preliminary evidence and future directions for those efforts.

Introduction

Methods for understanding the topics and concepts of individual publications are a matter of long-standing interest within the scientometric and informetric communities. Indeed, going back to some of Garfield's earliest thinking on citation indexes (1955), he identified a goal of an “association-of-ideas” index. In those thoughts he further developed the role such an index would play in the literature-search process and highlighted the value of a “sub-micro” or “molecular” level approach over one focused on “classification”.

Today document similarity and clustering is a vibrant area of research within the scientometric and informetric community and appearing in many contexts, including information retrieval, the mapping of science, and as an input to rich studies of the individuals and institutions engaged in the research production process. Much of today's work, in line with Garfield's early vision, finds citation and co-citation at the centre of their formulation of contextual or contextual similarity. Although that relationship may be more tenuous than generally accepted, see (Borner, Chen, & Boyack, 2003) for an in-depth exploration.

Increases in computational capacity and the availability of (electronic) data have opened many new avenues for estimating document similarity and carrying out clustering. While the range of options and ideas is vast, in this manuscript we focus on “Topic Models” –a group of techniques arising largely from the computer science literature. As the input to these techniques is textual data (specifically, a collection of text documents) they offer an interesting twist on traditional approaches for understanding the topics and concepts that make up individual publications and, in turn, estimating document similarities and clustering. As discussed below, these techniques are certainly not without their flaws[i] (Velden et al., 2017) but are also well positioned to exploit the rapidly growing body of textual, and perhaps even full text, data.

In this manuscript we develop a robust approach for calculating pair-wise similarities between documents based on state-of-the-art topic modelling techniques. We compute the similarity between researchers which, in turn, allows us to obtain the topical overlap (or proximity) between them.

With this text-only approach, we obtain a continuous knowledge domain space from which we can cluster and delineate topics as narrowly as desired, estimate interdisciplinarity, and observe the evolution and direction of research.

Background

Topic models are statistical models designed to extract from a set of documents the relevant "topics", and in turn, provide a representation of each document within that "topic" or latent space. More pragmatically, it is to infer from a set of document-term vectors a set of document-topic vectors (establishing the extent to which each topic pertains to each document) and a set of topic-term vectors (establishing the extent to which each topic is associated with each term). In this task, a topic model will exploit hidden semantic structure within and across the documents. As it is the case that each document is treated as a bag-of-words topic models cannot exploit local structure (*i.e.* grammar or the specific order of words within a sentence). But rather they exploit structure that emerge at the document level. For example, that the word "table" in the context of a document also containing the words "wood" and "legs" conveys a different meaning than "table" in a document containing "row" and "column". It is ultimately through the exploitation of high-level correlations in the co-occurrence of individual terms, as well as groups of terms, that the topic model produces its document-term and document-topic vectors.

In this manuscript we will test topic models in terms of their capacity to robustly estimate pairwise document similarities. Specifically, we have chosen Non-negative Matrix Factorisation (NMF) (Lee & Seung, 1999), Latent Dirichlet Allocation (LDA) (Blei, Ng, & Jordan, 2003) and doc2vec (Le & Mikolov, 2014). NMF decomposes the document-term matrix into a product of two matrices, which by design may have only non-negative entries. LDA is based on a probabilistic model of language in which decomposition stochastically produces two matrices. doc2vec is a relatively new neural network-based approach built upon the similarly new word2vec (Mikolov, Chen, Corrado, & Dean, 2013) word-embedding algorithm. doc2vec formulates the problem as one of predicting an omitted word within a short (3 to 15) contiguous sequence of text.[ii] Treating the neural network's hidden layer as the latent space, one can infer document-topic couplings from the model's parameters. Although it should be noted that, strictly speaking, doc2vec may not be considered a "true" topic model as the topic-term couplings are not easily inferred. But this is acceptable as the fundamental elements of the statistical analysis presented herein are document-document similarity scores, which require only the document-topic vectors.

A specific feature of most, if not all, topic models is that the size of "topic" (or latent) space must be defined by the user. Indeed, the question of what is the "best" or optimal size of the topic space comes up often, and no clear criteria exist (Glaser, Glanzel, & Scharnhorst, 2017). However, we propose this as a feature rather than a bug. Increasing the size of the latent space increases the granularity in which ideas are represented by the model. Considering all journal publications as the corpus, a topic space of size 5 would presumably decompose documents into the highest-level disciplines one may think of (*ex.* biomedical science, the physical sciences, social sciences, humanities, *etc.*) A latent space dimension of one or two hundred may decompose only well-established fields (*ex.* medicine, molecular biology, physics, economics, sociology, history, ...). But running the dimension up into the thousands, or even tens of thousands, allows one to identify very specific groups of research and researchers. For example, those working on a specific form of cancer within a specific model organism. Thus, the question of what is the correct number of topics should never be asked, but rather, one should ask, what is the proper number of topics to tackle your specific question.

Despite the many interesting questions that could potentially be attacked by pushing topic models to high dimensional topic spaces, they are rarely employed with latent dimension greater than, perhaps, a few dozen. This does not arise, however, from a lack of vision, but rather as one increases the number of latent dimensions the model, eventually, becomes unstable. To be very specific, at some point the exact same algorithm, with the exact same parameters, on exactly the same data, but with a different random seed will produce a quantitatively and qualitatively different set of document-topic and topic-term vectors (Belford, Namee, & Greene, 2017). In the topic modelling literature, a variety of information-theoretic measures have been proposed for estimating the extent to which topic-term vectors vary from run to run. However, it is indeed that case that changes in the topic-term vectors may *not* preclude stability when considering only document-document similarities. That is, even if the topics themselves are inconsistent from one training to the next, the measure of pairwise similarity may not change.

Analysis

To be suitable for application in scientometrics it is our view that it must be demonstrated that topics models possess three properties:

- Statistical robustness. That is, running the same model on the same data with the same parameters should produce the same, or at least highly similar results.
- Descriptive power increases with the size of the latent dimension. That is, changing the number of topics should alter the results both qualitatively and quantitatively.
- Reflect reality. That is, the results produced by topic modelling, be they document-document similarities or clustering or otherwise, must be consistent with patterns and relations known to exist within and across research domains.

Below we propose and execute specific statistical tests concerning the first two, while for the third we provide preliminary evidence and highlight paths for further work. However before getting into the analysis, we will define the specific data and context in which we are working.

Data and Methods

In the analysis below a document is the career output of a researcher and the terms are Medical Subject Headings (MeSH). The output of each researcher is taken from the Author-ity disambiguation of PubMed carried out by Torvik and Smallheiser (2009). For each researcher, we extract from their publications all assigned MeSH. To be explicit, the document-term vector resulting from this procedure is one in which each vector entry corresponds to the number of times a given MeSH was assigned to the given researcher's publications across the entirety of his or her career. Disambiguation is thus crucial for reliability of the models. We deal with careers starting 1974 or later, noting that our data terminates in 2009 as that is when the disambiguation ends. Our full corpus comprises about 147000 researchers, however in many analyses below we focus on a subset of 13900 researchers in the Neurosciences. This choice was based purely on a desire to reduce the scale of the analysis to one in which all pairwise similarity scores can be calculated in a manageable amount of time.

As mentioned previously we explored the performance of three topic modelling approaches: NMF, LDA and doc2vec. We performed tests with similar latent space sizes (around 400), multiple iterations and negative sampling when available.

Statistical Robustness

We propose to evaluate the statistical robustness of a topic model via the extent to which it produces consistent estimates of pairwise document-document similarities. Being more specific, as a given model is retrained using the same parameters and data, one can track the mean and standard deviation of the cosine similarity of each pair of documents. If perfectly robust, a model would produce exactly the same similarity each time. An imperfect, but still useful, model will produce slight variations in the each pairwise similarity, but over many retrainings, converge to a specific similarity value for each pair.

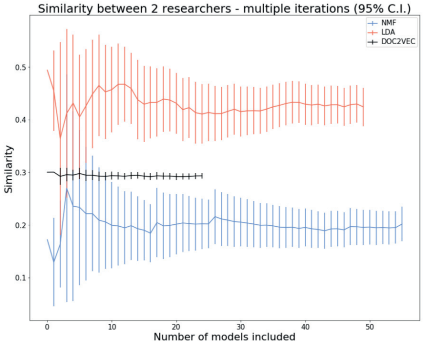

Figure 1 Cosine Similarity between 2 researchers across different models averaged under many retrainings.

Figure 1 shows the behaviour of a specific researcher-researcher similarity score produced by NMF, LDA and doc2vec under many retrainings. First note that each of the three topic models produces a different similarity score, despite having the same number of topics (NN). Second, and most importantly, note that the similarity score for NMF and LDA have a far larger range of results than doc2vec, and display weaker convergence. It is indeed the case that this figure is representative of the behaviour of the three models across all researcher-researcher pairs as well as a wide range of latent space sizes.[iii] Thus NMF and LDA are not statistically robust, while doc2vec warrants further analysis.

Descriptive Power

To get a handle on the descriptive power of doc2vec (or any topic modelling approach) we propose a straightforward procedure based on principal component analysis (PCA). In this approach PCA is first carried out on the document-topic vectors (researcher-topic vectors in this instance). The principal components are then ordered by explained variance and their cumulative explained variance is plotted in Figure 2.

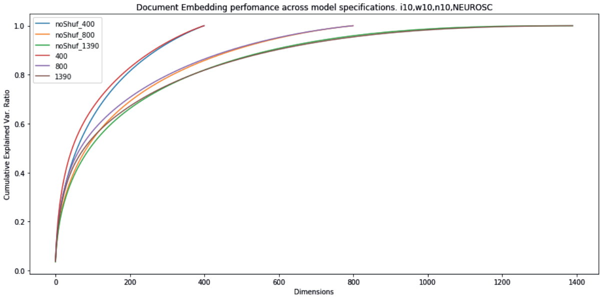

Figure 2 Explained Variance (%) of PCA-transformed embeddings

The PCA explained variance plot allows us to understand the extent to which each dimension allows differentiation among documents vis-à-vis the latent space. For example, a perfectly straight line running from the lower left to the upper right would indicate that each dimension contributes equally to explaining the variation among researchers, and hence, allow for the differentiation between researchers. On the other hand, a curve that quickly reaches 1.0, perhaps after only N dimensions, indicates that only those first N dimensions are actually contributing to explaining the variance.[iv] Or in other words, all dimensions beyond the first N are useless. Thus, the explanatory power of a given topic model can be measured by the area over curve (AOC) in such an explained variance plot. In Figure 2 we see that the doc2vec models do diverge from perfect, but still, a good 20% of the variance does reside in the last ~900 topics of even the most extreme models considered.

Concordance with reality

Properly reflecting reality is, of course, the most important criteria for approach for generating an abstract representation of data. It is often also the most difficult however. Here we provide two small examples as evidence that, at the very least, the results do not directly oppose expectations.

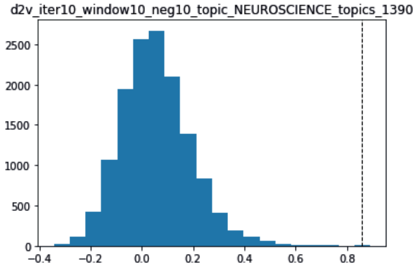

Figure 3 Distribution of cosine similarities between a specific researcher and all other researchers. Dotted line highlights similarity with this researcher's early-career PI.

In Figure 3 the distribution of cosine similarity between a given researcher and each other researcher in the corpus is shown. On the far right, the dotted line highlights the researcher's similarity with a PI from her or his early career. As one would expect, this researcher's highest similarity is, indeed, with his or her early career mentor.

Going forward we are pursuing 3 main avenues of analysis for evaluating the extent to which document similarities produced by doc2vec reflect reality. The first avenue involves using external information to identify pairs of documents that should be highly similar and valid on the doc2vec based similarity measures. In the case of researchers, as shown above, early career mentors represent a set that should be highly similar. In the case of individual publications, those arising from the same grant represent a group of highly similar documents (Boyack Kevin W. AND Newman, 2011). The second avenue involves validation by individuals with significant domain knowledge in each of a variety of fields. Third, using similar methodology clustered at the journal-year level, we observe how the same journal in consecutive years show high similarity.

Conclusion

Topic models are powerful statistical techniques with great potential to contribute to scientometrics, especially as textual data becomes more available going forward. However, they also suffer specific flaws that must be carefully weighted against the benefits. In particular, establishing statistical robustness is challenging, evaluating their descriptive power is key, and ultimately verifying they reflect reality is clearly necessary.

In this manuscript we have proposed a simple approach for estimating the statistical robustness of topic models that is based on pairwise similarity scores between documents. Applying that method, we found that Non-negative Matrix Factorisation and Latent Dirichlet Allocation do not appear to be especially robust for large latent spaces (dimension far greater than 10). doc2vec, a neural network-based approach does, on the other hand, appear to produce relatively stable estimates of pairwise similarity.

We further proposed a principal component analysis-based approach for assessing the descriptive power of topic models. Applying that method to researcher-topic vectors obtained from doc2vec we find that, while doc2vec does not produce perfect results descriptive power does persist into the highest dimensions of the latent space.

In terms of the extent to which doc2vec results reflect reality, many questions remain. We provided two small pieces of evidence that what doc2vec produces is not completely out of bounds. However, careful quantitative validation is still required.

Abstract

The paper examines current performance assessment practice in Europe: first, it identifies those bibliometric methods that are used most often, and second, it identifies those actors who have been able to define current practice. The paper draws on Abbott's theory of professions and argues that indicator-based research assessment constitutes a potential jurisdiction for both individual experts and expert organizations. The paper presents a search methodology that yielded 82 professional evaluation studies from 14 EU countries, covering the period 2005 to 2014. Using structured content analysis, our findings are as follows: (1) Bibliometric research assessment is most frequently used in the Netherlands, the Nordic countries, and Italy. (2) The Web of Science (WoS) is the dominant database for the assessment of public research in Europe. (3) Expert organizations invest in improvement of WoS citation data and are able to set technical standards with respect to data quality. (4) Field averages are the most frequent frame of reference for citation impact. (5) The WoS classification of science fields (SCs) functions as a de-facto reference standard for research performance assessment. In light of these findings, the paper discusses the importance of data access and transparency for the development of professional bibliometric assessment.

Introduction

There is a growing demand for practicable methods in research evaluation on the part of research organizations and research funding agencies, including metrics based on publication and citation data (bibliometric indicators). Among the scientific communities affected by performance assessment, bibliometric indicators have remained controversial (Adler, Ewing, & Taylor, 2009; Bonaccorsi, 2018; Cagan, 2013; de Rijcke, Wouters, Rushforth, Franssen, & Hammarfeldt, 2016). So far, there are no widely agreed upon standards for bibliometric research assessment. Against this background, the present paper investigates two research questions: First, which methods of bibliometric performance assessment are prevailing in research evaluation practice? Second, if certain de facto standards of bibliometric research assessment can be observed, which social actors have been able to define them?

While there have been several reviews on scientific developments in the area of evaluative citation analyses in recent years (EC, 2010; Mingers & Leydesdorff, 2015; Todeschini & Baccini, 2016; Waltman, 2016; Wilsdon et al., 2015), there is little overview so far on which methods are actually used in bibliometric assessment practice. Methodologically, the present study resembles a meta-evaluation or evaluation synthesis. The expression 'meta-evaluation' is commonly used in the literature to denote systematic reviews of evaluation studies with respect to their methodological quality and results (Cooksy & Caracelli, 2005; Stufflebeam, 2001). The present study also analyses the methods used in existing evaluation studies from a meta-perspective. But rather than assuming predefined methodological standards of good practice and evaluating published studies accordingly, the purpose is to find out what methodological standards existed in the field of assessment practice during a certain period and who shaped them. These are referred to as professional de facto standards.

This paper is part of a project seeking to understand the development of bibliometric assessment methods from the perspective of Abbott's sociological theory of professions (Abbott, 1988, 1991). This theory was chosen to investigate how particular methodological choices become socially established as professionally legitimate means of treating certain types of evaluation problems. More specifically, this framework is used to address the question of professional control in bibliometric assessment. In Abbott's terminology, the increasing demand for practicable and efficient assessment of academic performance constitutes a problem amenable to expert service. Thus, research assessment constitutes a potential jurisdiction for professional experts who are capable at defining the nature of assessment problems as well as offering solutions that effectively adress client´s needs. A recent paper investigated empirically whether the academic research area of evaluative citation analysis (ECA) has been able to define scientific standards for the practice of bibliometric research evaluation in the period 1972-2016 (Jappe, Pithan, & Heinze, 2018). Based on the theory of intellectual fields as reputational organizations (Whitley, 2000) and on an organizational network analysis, this study concluded that the research area of ECA has been characterized by low levels of reputational control, as evident from high shares of outsider contributions and new actors entering the field over the whole period. It was argued that the observed lack of reputational control within the academic research area is at least consistent with observed difficulties in establishing scientific authority for bibliometric assessment practice.

Continuing this line of inquiry, the current paper investigates whether professional evaluation practice is characterized by at least de facto standards of bibliometric methods. For this purpose, we conducted a content analysis of professional evaluation studies published in European countries in the period 2005-2014. We focus on the measurement of citation impact as practiced in real evaluation studies. Other topics of bibliometric assessment such as emerging research topics, research profiles, or international collaboration are not part of this study. Our initial assumption was that leading organizations within the expert field take the role of defining de facto standards, first because they have a high market share of assessment services and second because they serve as a legitimate role model that is then imitated by other bibliometric experts. Our study sample includes a total of n=82 individual studies evaluating either research organisations (RO) or research funding instruments (FI) from 14 European countries plus EU framework programs. An important selection criterion was that each study had been conducted for purposes of decision-making in research policy or research management. The paper first presents theoretical considerations concerning the application of professional sociology to the field of bibliometric research evaluation, then describes data and methods of our analysis, including search strategies, selection criteria and the content analysis of evaluation studies with respect to their methodological design and metrics, followed by a presentation of the empirical findings and a discussion of the results in the light of the theoretical framework. The present version of the paper includes two selected data tables. More detailed results will be shown in the conference presentation.

Theoretical Considerations

Abbott's theory of professions is a sociological framework for analyzing how professional expertise is socially constructed and institutionalized in modern societies (Abbott, 1988, 1991). The analysis starts with a societal problem amenable to expert service and with groups of professional actors who claim relevant expertise for treatment of this problem. The theory distinguishes cognitive claims for expert knowledge from social claims for jurisdiction for problem diagnosis and treatment that professionals need to establish in various social arenas, including the legal system, the public, and the workplace. The concept of a professional jurisdiction goes beyond a merely economic notion of a market for expert services by inquiring into the development of expert control concerning appropriate problem definitions and treatments from a socio-historical perspective. The framework is also suitable for cross-national comparisons since it does not make specific theoretical assumptions concerning the role of the nation state for the eventual settlement of professional jurisdictions in different countries. The conceptual framework was chosen for the present project because it is suitable for the investigation of emerging professions that do not yet possess recognized domains of expertise, which might eventually be protected by state licences, but are still engaged in an ongoing competition with other professional actors for the appropriation of relatively new jurisdictions or tasks.

Applying this theoretical framework, we assume that a demand for professional services in the realm of quantitative research assessment arises mainly on the part of research organizations and research funding agencies as the two most important groups of potential clients. These organizations have a demand for reliable information concerning the performance of their scientists, research groups or funded projects for purposes of decision making (Miller, 2013; H. F. Moed, 2005), and for accountability and legitimacy (Power, 1997; Strathern, 1996). Thus we assume that demand is mostly located at a meso-level of organizations in the public research system. Although private firms also use bibliometrics, information on research performance assessment in the private sector is not systematically accessible and therefore not part of the present study. Several European countries are also experimenting with the introduction of bibliometric methods for performance based institutional funding on a national scale (Ancaiani et al., 2015; Hicks, 2012; Sivertsen, 2016, 2017). The country with the most extensive use of bibliometric performance measurement during our observation period was Italy. The Italian National Agency for the Evaluation of Universities and Research Institutes (ANVUR) was created in 2006 with the mandate to evaluate all public research, an exercise called “Valutazione della Qualità della Ricerca” (VQR) (Ancaiani et al., 2015). Bibliometric reports for the first round of the VQR, covering the period 2004-2010, were included in this meta-evaluation.[1] National evaluations with a disciplinary scope by the Nordic Institute for Studies in Innovation, Research and Education NIFU were also included. In the UK, the introduction of bibliometric methods for the Research Excellence Framework (REF) has been intensely debated since 2006 (Arnold et al., 2018). The methodological framework for the upcoming REF exercise in 2021 prescribes that disciplinary sub-panels may use citation data which will be centrally provided by the REF “where appropriate and available (…) to inform their assessment of output quality” ((REF, 2019): 36; 50).

According to Abbott, the work of professionals can be generally described as the application of abstract knowledge to complex individual cases. Abstract knowledge is an important source of legitimacy for claims to jurisdiction because it ties professional work to the general values of logical consistency, rationality, effectiveness, and progress. This scientific legitimacy includes a definition of the nature of problems, rational means of diagnosing them, and the delivery of effective treatment. In addition, abstract knowledge enables the instruction and training of students entering the profession and is oriented towards generating new mechanisms of diagnosis, inference, and treatment. Abstract knowledge is typically produced by an academic sector closely related to the profession. A recent study investigated the academic research area of ECA as the academic sector which is closely aligned with bibliometric evaluation practice (Jappe et al., 2018). Abstract knowledge is also stored in specialized artefacts which Abbott refers to as expert commodities. In the case of evaluative bibliometrics, citation databases, such as Web of Science (WoS) or Scopus, are the most important artefacts for professional work.

The present study observes professional practice by means of examining a set of professional evaluation studies. These studies evaluate the performance of either RO or FI in Europe based on publication and citation data and have been published either in the format of study reports (grey literature) or as journal articles. Bibliometric experts and expert organizations are encompassed as authors of these studies, while RO and FI are encompassed as evaluation objects, but also in many cases also contracting entities of the respective studies. This definition of professional practice excludes all usage of bibliometric indicators that is less explicitly codified, as for example in cases when RO use internal metrics to evaluate staff performance, or in cases when funding agencies use the journal impact factor or the h-index to make selection decisions among program applicants without publishing them. The study is confined to Europe, i.e. evaluation objects must be located in a European country. In this way, the analysis of widespread assessment practices also contributes to the investigation of commonalities in an European research area.

Data and Methods

The current section describes the selection criteria for inclusion of studies in our analysis, the search strategies to identify such studies, and the coding scheme and procedures used to extract methodological information from each individual study. The sampling strategy did not aim at statistic representativeness but at the identification of as many incidents of bibliometric evaluation as possible from diverse sources. The selection criteria were as follows:

1. Each evaluation must include a publication and citation analysis. The sample includes both studies that rely exclusively on bibliometric data as well as multi-dimensional evaluations that combine bibliometric data with other information such as peer

evaluations, financial and personnel data, case studies etc. (Martin, 1996; H. Moed & Halevi, 2015). In either case, only the bibliometric analyses are object of the content analysis.

2. The objects of evaluations are either research organizations, ROs (typically universities and/ or their departments or faculties or extra-university public research institutes) or funding instruments, FI (typically aimed at supporting research projects or individual researchers at public RO, sometimes involving private firms, and sometimes supporting more long-term investments such as excellence schemes).
3. Evaluation objects must be located in Europe.
4. The evaluation was conducted with the stated purpose to inform decision making on behalf of the respective RO or FI. Purely academic studies on the basis of bibliometric data were excluded from the study sample.
5. The evaluation has been published between 2005 and 2014, including grey literature (project reports) as well as journal articles.

Multiple search strategies were combined in order to identify as many studies as possible:

1. Prior research identified expert organizations and individual experts with a central position in the academic research area of ECA (Jappe et al., 2018). A request for non-confidential evaluation studies was sent to experts in 35 research organizations in 13 European countries. 18 organizations responded (51 %) of which 11 (31 %) contributed evaluation reports or shared information on published studies. In total, 16 studies (20 %) of the eventual sample have been identified in this way.
2. Evaluation studies were extracted from a set of WoS publications identified as "follow-up research on citation impact indicators" (Jappe et al., 2018). This set includes all publications in WoS that cite any of 169 specified citation impact indicators, a total of 2757 publications from 2005-2014. Keywords and journal titles were analysed in order to identify relevant studies from this sample. From an initial set of 315 potentially relevant publications, 15 evaluation studies have been retained (18 % of study sample).
3. The "Science and Innovation Policy Evaluation Repository" (SIPER) was searched for bibliometric studies. This publicly accessible database contains meta-data and in part also original documents of evaluation studies. A search for citation analysis retrieved 24 potentially relevant documents, three of which were eventually retained (4 % of study sample).[2]
4. Prior research investigated the history of CWTS as an expert organization in the field of evaluative bibliometrics (Petersohn & Heinze, 2018). In the course of fieldwork, the authors obtained 24 evaluation reports by CWTS (29 % of study sample), as well as three more evaluations by other bibliometric authors (4 %).
5. The Italian public agency ANVUR has the legal mandate to evaluate the quality of activities by all RO receiving public money, as well as FI aimed at research and innovation (ANVUR, 2013). The first round of VQR, covering the period 2004-2010, was included in the content analysis, while the reports of the second and third round were published after 2014. Among 14 disciplinary areas in the Italian system, nine applied bibliometric assessment. Since each disciplinary committee has the mandate to decide upon the appropriate evaluation criteria within its field(s) of research, the reports for the different sectors were treated as individual bibliometric exercises for the purpose of this content analysis. In this way, the VQR contributed nine individual studies to the study sample (11 % of study sample).
6. The worldwide web was searched for evaluation reports by funding agencies. Some countries and agencies follow high standards of transparency concerning the evaluation of

public research, including e.g. the Swedish Council for Science (Vetenskapsradet VR), the Swedish Environmental Protection Agency (SEPA), the Danish Council for Strategic Research, or the British Wellcome Trust, among others. In total, web searches identified 12 relevant and publicly available evaluation reports (15 % of study sample).

The final sample includes 82 distinct bibliometric studies of which 58 (71 %) evaluate RO and 24 (29 %) evaluate FI. Three expert organizations stick out in particular. CWTS is the organization with the largest share of studies (n=24), followed by ANVUR VQR (n=9) and NIFU (n=7). Since the studies from the same organization use identical citation impact metrics (CWTS, NIFU), or share at least important characteristics (VQR), the respective subsets are analyzed separately on some dimensions from the remaining 42 studies, the latter subset is referred to as studies "by other bibliometric experts". All evaluation studies are documented in the Annex to the paper as currently under preparation for journal publication.

Methodologically, our study is based on a structured content analysis. The bibliometric design of each individual study was analyzed with a scheme of 37 coding questions in ten topical areas. The topics include (1) bibliographic information on the individual study, (2) the professional setting, (3) the object of evaluation, (4) the citation databases, (5) quality enhancement of bibliometric raw data, (6) sampling strategy and data collection, (7) research areas under study, (8) definition of citations, (9) citation impact indicators, and (10) statistical methods used. The definition of variables follows the methodological literature on citation analysis, especially (H. F. Moed, 2005; Todeschini & Baccini, 2016; Waltman, 2016). Most items are on nominal level of measurement, i.e. non-ordered qualitative characteristics. Five items are formulated as open questions, so that raters could write down more detailed information. This coding scheme was developed in an iterative procedure beginning with a partial sample. In order to test interrater reliability, the initial coding scheme was applied by two raters to an initial sample of 20 different studies. Where differences in coding became apparent, they were discussed among the two raters and the items improved in order to reduce their ambiguity. The remaining studies were each coded once by the author.

Results

1. Bibliometric research assessment is most frequently used in the Netherlands, the Nordic countries, and Italy.

Although we found instances of bibliometric evaluation in many European countries, more regular use of bibliometric assessments has been concentrated in a few countries during the observation period. Overall, the sample includes studies from 14 countries plus Framework Programs of the European Union, approximately 60 % of the studies come frome the Netherlands, Italy, Sweden, Norway, Finland, and Denmark. The Netherlands and the Scandinavian countries are medium-size research systems with a strong performance (particularly Denmark and the Netherlands) in international comparison. Among the larger public research systems in Europe, Italy is the only one with national-scale bibliometric assessment. The UK Research Excellence Framework uses bibliometric data only to inform peer review (Arnold et al., 2018; REF, 2012, 2019), and Germany has no national framework for research evaluation. Our search strategy did not yield any bibliometric assessments for France.

Coverage of individual nations does not only represent the diffusion of bibliometric methods but may also result from different publication policies. For example, evaluations of Max-Planck-Institutes in Germany are usually kept confidential. By contrast, in Sweden, publication is mandatory under national transparency rules, so that many evaluation reports are available on the internet. However, there is no reason to assume that bibliometric techniques differ systematically between confidential sources and published reports, except for the reported level of aggregation. For example, reports by CWTS and the Italian VQR do not contain information on individual researchers or research groups.

2. The Web of Science (WoS) is the dominant database for the assessment of public research in Europe.

During the observation period, the citation indices contained in the WoS provided the basis for the bibliometric evaluation of public research in Europe. 90 % of all studies in the sample rely on WoS, while only 15 % use Scopus or a combination of WoS and Scopus. In some cases, designated databases such as PubMed or MathSCInet are employed, but these alternative citation databases exist in only a few disciplines. In other cases, citation data are complemented by national databases that are more comprehensive in terms of research products, but do not contain original citation data. Two examples are the Norwegian Current Research Information System (Cristin), which includes a larger array of document types such as books and book chapters (Sivertsen, 2016), and the Italian VQR that includes all types of research outputs, e.g. software, patents, maps or artworks (ANVUR, 2013).

3. Expert organizations invest in cleaning and improvement of WoS citation data and are able to set technical standards with respect to data quality.

Citation raw data as provided by WoS or Scopus require considerable processing before they are adequate for the assessment of authors and research organizations. The main problems are the ambiguity of author names and institutional addresses as well as the unambiguous assignment of authors to research institutions. In particular, variants of institutional names require detailed knowledge of national research systems for correct disambiguation. These and other technical problems also lead to certain proportions of false citation linkages in the raw data. Expert organizations such as CWTS and NIFU, but also the Italian CNR-IASI, the German Max Planck Society and the German Competence Center Bibliometrics currently deal with this situation by buying raw data from database providers (Clarivate Analytics, formerly Thomson Reuters, sometimes complemented by Scopus Elsevier) and then construct in-house databases with improved data quality. The studies by the other bibliometric experts also frequently mention the effort required for disambiguation of author names and institutional addresses. Also, one of the main practical arguments for the H-index is its alleged robustness with regard to incomplete publication and citation data.

4. Field averages are the most frequent frame of reference for citation impact in professional evaluation studies.

In order to analyse how the frame of reference was conceived in bibliometric studies, we analysed their evaluation objects and choice of metrics in more detail. Concerning evaluation objects, ROs were differentiated according to scale (number of institutes or universities) and scope (mono- vs. multi-disciplinary), while FI were distinguished according to funding units (research projects, scientists, ROs, portfolios). Concerning the choice of metrics, we distinguished impact metrics based on “international field averages” from impact metrics based on “national rankings” and “other”. International field average means that observed citation rates are assessed with reference to citation rates for the same research field and the same period (sometimes also the same document type) in the entire database. This is also refered to in the literature as a comparison of observed to expected citation rates, where the database field average stands for average expected citation rate (H. F. Moed, de Bruin, & van Leeuwen, 1995; Waltman, 2016). This type of metric is used in 65 % of the study sample, including all 31 studies by CWTS and NIFU. National rankings represent a different approach where the relative national position is the frame of reference for research performance. This type of metric is used only in the evaluation of Italian university departments, or 12 % of the studies. Other frames of reference include mainly journal impact based measures and h-type indices, but also some quasi-experimental group comparisons (funded vs. non-funded scientists) in FI studies (Table not included).

5. The WoS classification of science fields (SCs) functions as a de-facto reference standard for research performance assessment.

In principle, field normalization is applicable to different types of citation metrics (Waltman, 2016), including journal impact, arithmetic mean, highly cited percentiles, as well as h-type indices, or indirect citation metrics. Solely source normalized impact metrics are construed as a methodological alternative in order to avoid problems of field normalization (Waltman & van Eck, 2013). Yet only some of these possible combinations are actually found in our sample (Table 1). Field normalized arithmetic means are the single most frequent type of metric (65 %), often combined with top-percentiles, as practiced by CWTS, among others. The h-index and other h-type indices (g-index) occurred in 18% of studies, mostly by other bibliometric experts; a field-normalized h-index appears only once. Source normalized indicators were not used by a single study, and only one study applied an indirect citation indicator. The category of "other indicators" includes different metrics. For example, in the case of VQR this refers to the construction of composite indicators for university rankings. In the case of CWTS, this category includes the normalization of citation impact with reference to the journal set in which a group has published. In general, it can be concluded from the overview in Table 1 that few of the methodological improvements recently proposed in the academic debate on impact metrics (Jappe et al., 2018; Todeschini & Baccini, 2016) have made their way into research assessment practice during the period observed.

Journal impact continued to be used quite frequently (46 %), even though the substitution of the impact of the publishing journal for the actual number of citations of an article has repeatedly been critized for lack of validity (Table 1). Journal impact is used in order to substitute missing data, either because publications are so recent that actual citations are not yet available (e.g. VQR), or because articles are published in journals that are not covered by the database (e.g. NIFU, VQR). Another reason is comparatively easy access of journal impact metrics via Journal Citation Reports, which is relevant especially for bibliometricians without fully licensed access to citation databases. Sometimes journal impact is used in a pragmatic way, just distinguishing two levels of journal quality (NIFU).

In total, field normalization, here including the field normalized arithmetic mean and other field normalized percentiles, was used by 84 % of all studies (Table 2). Of those 69 studies, 84 % rely on the WoS classification of science fields (WoS subject categories), plus an additional 3 % that use the related Essential Science Indicators classification by Clarivate Analytics (formerly Thomson Reuters). The Scopus science classification is mentioned mainly in the Italian VQR reports. 13 % of field normalizations are based on self-defined journal sets, or keywords in combination with self-defined journal sets, and some studies used more than one field classification. Alternative field taxonomies proposed in the academic literature have attained little influence so far. Few studies use discipline-specific databases and subfield classifications. It can be concluded that the WoS classification of science fields has attained the status of a de facto reference standard, at least for the time period under study.

Table 1: Types of impact metrics used in evaluation studies

	Type of metric	*VQR*	*CWTS*	*NIFU*	*Other bibliometric experts*	*Studies total*	*% studies*
1.	Journal impact	9	0	6	23	38	46
2.	Field normalized arithmetic mean	0	24	7	22	53	65
3.	Other field related percentiles (e.g. top highly cited)	9	21	0	13	43	52
4.	H-index and h-type indices	0	1	0	14	15	18
5.	Indirect citation impact	1	0	0	0	1	1
6.	Source normalization	0	0	0	0	0	0
7.	Other metrics	9	23	5	8	45	55
8.	More than one type of metric	9	24	6	27	66	80
	Studies total	9	24	7	42	82	100

Discussion

The findings of our analysis support our initial assumption that leading expert organizations have an important role in defining de facto standards. The prominent position of individual expert organizations in the field is well documented by the study set. The two most prominent organizations according to this study are CWTS and NIFU, both of which have regularly conducted bibliometric assessments for many years and produced important shares of the data set. These expert organizations are able to define technical standards with regard to enhanced quality of publication and citation data. Following the example of CWTS, not only NIFU, but also other expert organizations such as the Italian CNR-IASI, the German Max-Planck Society, the German Competence Center Bibliometrics, and other institutes invest heavily in inhouse-databases in order to clean WoS raw data. The same level of data quality cannot be attained by bibliometric experts without equivalent databases, at least not for larger publication quantities.

Our assumption that prominent expert organizations are imitated and that their approach gains legitimacy within a field as an instance of recognized expert practice is most likely true with respect to the broad dissemination of the field-normalized arithmetic mean. In this case, the role model is CWTS which, although not having invented the idea of observed versus expected mean values, was first in Europe in starting to use such indicators systematically on the basis of an inhouse database in the early 1990s (H. F. Moed et al., 1995). This finding is qualified by the fact that the Italien VQR deviates from the professional standards as modeled by CWTS and more generally from the methodological debates in the academic field of ECA.

Many alternatives and refinements of field-normalized mean indicators have been proposed in the academic literature, including the h-index as the most cited methodological alternative and source normalized indicators as a way to avoid problems of field normalization altogether (Jappe et al., 2018) This debate is consistent with the Abbott's proposition that the academic sector would invent new methods and that experts would make competing cognitive claims. The subset of studies by "other bibliometric experts" displays more heterogeneity with regard to citation impact metrics and field classifications than the total sample. This greater methodological diversity suggests that the expert field as a whole did not produce a clear challenge to the predominant approach in the emerging jurisdiction. Thus despite existing criticisms, neither of these alternatives was able to overtake the prominence of the field-normalized arithmetic mean as a recognized professional practice. But neither did the expert field collectively adopt one standard methodology for bibliometric evaluation.

Beneath a surface of methodological diversity and academic openness, this analysis unequivocally documents the predominance of the commercial database WoS with respect to the definition of methodological standards for performance assessment of public research in Europe. During the observation period, the provider of WoS assumes the most important role in defining de facto standards for bibliometric assessment. All expert organizations, including CWTS and NIFU, base their citation analyses on data licensed by Clarivate Analytics, and this is also true for almost all other bibliometric experts. But not only does Clarivate Analytics (via its licencing policy) regulate to which extent different user groups have access to citation data, but WoS science categories function as de facto reference standards for bibliometric assessment. In addition, there is the effective dissemination of selected impact indicators via the Journal Citation Reports and Incites. It appears that all efforts on the part of academic bibliometricians to develop alternative categorizations of scientific fields (Shu et al., 2019) or more complex impact indicators have had little impact on professional practice so far because they cannot be distributed alongside with citation data. The few examples for the use of alternative or supplementary sources such as the specialized citation database Medline/Pubmed or the research documentation system Cristin underline that bibliometric evaluation practice depends first and foremost on the data sources that are accessible for comparative analyses of research performance. While some studies in the literature investigated within-field homogeneity and across-field heterogeneity of citations in WoS subject categories (Albarrán, Crespo, Ortuno, & Ruiz-Castillo, 2011; Leydesdorff & Bornmann, 2016; Wang & Waltman, 2016), the adequacy of this classification as the main frame of reference for the evaluation of scientific impact has not been established.

Abstract

As the figure and role of Research Organizations is increasingly changing in the last decades, the way we categorize this kind of institution is becoming more challenging. This article aims to differentiate profiles of European Research Organizations considering their performance in terms of bibliometric indicators. The indicators are associated with scientific impact, international collaboration and industry links. The results of a k-means cluster analysis shows three distinctive groups of institutions that can be described by their levels of impact, international collaboration and industry collaboration. As expected, we found a correlation between organizations collaborating internationally and having a high impact research output. The analysis opens up the possibility of identifying well defined groups of Research Organizations based on bibliometric indicators.

Introduction

The terms ‘Public Research Organizations’ (PROs) or Public Research Institutions (PRIs), are broadly used concepts to define this institution type. However, they are slowly and inevitably becoming difficult to apply when addressing them, especially when referring to their different degrees of publicness. According to Bozeman & Bretschneider (1994) few, if any, complex organizations are purely public or purely private. Instead, some mix of public and private authority influences the behavior of most organizations. The term Research Organizations as such, once represented by a more homogenous group, have experienced a diversification of role, mission, source of funding and the collaboration schemes at national and international level. This transition has been well documented in recent decades, whether in institutional reports or scientific articles (OECD, 2011; Cruz-Castro, Jonkers & Sanz-Menéndez (2015); Bodem *et al.* (2006); Peñasco, Sanz-Menéndez, Cruz-Castro & Martínez (2017). In this article, we address them by using the term Research Organizations (RO) as a more inclusive concept that encompasses increasingly privately funded and autonomous institutions referred to as “semi-public”.

In 2015 the OECD published the last edition from The Frascati Manual, with its first version dating back to 1963. This manual is considered the main guideline for evaluating R&D activities, being the bibliometric analysis one of the indicators that provide users and producers of R&D statistics a context for setting measurements within the framework of the overall S&T system. These indicators can be applied at different levels, assessing research performance of individuals/research teams, institutions and countries, to identify national and international networks, and to map the development of new (multidisciplinary) fields of science and technology (OECD, 2002). In terms of institutional sectors, the Frascati manual encloses the following units: *Business enterprise (BE), Government (GOV), Higher Education (HE) and Private non-profit (PNP).*

The roles and structures of research organizations are constantly transforming, and as such, novel paths and models have risen seeking to close the gap between this traditional classification and new exploratory approaches to group and distinguish them. In 2010, Arnold *et al.,* identify three types of PRO: government laboratories, scientific research institutes and research and technology organizations. Afterwards categories proposed by OECD (2011) involving MOCs (Mission-Oriented Centres), PRCs (Public Research Centres and Councils), IRIs (Independent Research Institutes) and RTOs (Research Technology Organizations) are seen as ideal types of PROs. While some organizations fit into these categories in a straightforward manner, the classification becomes complex for other organizations. This is mainly due to the nuances or ownership and control by government bodies. As stated in the Frascati Manual "*It should be noted that in some cases the definition of control is challenging, because the power to decide on the allocation and amount of funding can be a major means of control. Therefore, it can be appropriate to use the major source of funding as an additional criterion to decide whether the institution is government controlled or not*". It is worth pointing out that finding information related to the source of funding for organizations implies an arduous effort and most of the time this information is not reachable using conventional methods.

As seen in figure 1, ROs spread and interact throughout different sectors, emphasizing the multisector profile of the Research Institutions. The links depicted in figure 1 are based on the definition and identification of every category extracted from the Frascati Manual (2015) and OECD (2011).

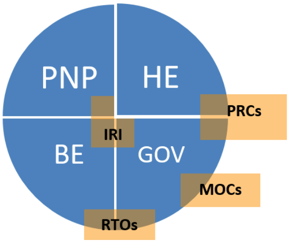

Figure 1. Relationship between unit sectors from FRASCATI (2015) and Public Research Organizations (OECD, 2011) (Source: Author)

In 2017, Peñasco *et al.* developed a novel attempt of providing new categories that would explain the main characteristics of Research Organizations. This classification was based on qualitative aspects such as their mission, legal status and ownership among other criteria. A cluster analysis determined a total of four different groups as follows: Hybrids (HYB), Research Councils (REC), Technology Oriented Centres (TOCs) and Government Laboratories (GOL).

One of the criteria that may not be fully captured in the previous classifications, or at least not directly, is the process of internationalisation/Europeanisation of institutions. This, among other reasons, is an adaptation strategy of a changing research policy scenario (Cruz-Castro, 2015). According to a study developed by OECD and published in 2011, a surveyed list of Public Research Institutions described the methods of international linking as varied, ranging from informal exchange and researcher interaction on projects, to collaborative centres. The same study observed the tendency of having more diversified international linkages for entities with multiple research areas and intensive academic orientations. There are also instances of nationally funded organizations that have been able to evolve into a type of global actor and change some of their functioning rules (for example, the German Max Plank Society (MPG) or the French National Center for Scientific Research (CNRS). As a general rule, those PROs fundamentally financed through project-based funding and have small proportion of their funding portfolio coming directly from the state, face greater incentives to internationalise via fundraising or fund applications. Zacharewicz, Sanz Menendez & Jonkers in 2017 claimed Research Technology Organizations (RTOs) have progressively extended the scope of their activities outside their country of origin, motivated by producing excellent and high impact R&I while solving societal challenges and boosting industry's competitiveness.

The research in progress presented here aims to explore underlying structures or groups of ROs, relying on bibliometric indicators as the source of analysis. This, in order to achieve a deeper understanding of ROs in terms of publicness, internationalization and impact from the research performance perspective. For the purpose of obtaining quantitative measurements of the three aforementioned topics we selected one bibliometric indicator per matter. In this way, the **PP(Industry)** indicator**,** was chosen to quantify links with the private sector and therefore a way of indirectly measuring the degree of publicness shared by ROs. The **PP(Int_collab)** reflects international collaboration among institutions and **PPtop5%** to approximate measurement of scientific impact based on citation counts. Further efforts aim to determine to which extent these different profiles of ROs can relate to other current classification of Research Organizations.

Method

This study focuses on publications in journals processed for the Web of Science's (WoS) database produced by Clarivate Analytics. The indexes used are the Science Citation Index (SCI), Social Science Citation Index (SSCI), and the Arts & Humanities Citation Index (A&HCI). The Conference Proceedings Citation Index-Science (CPCI-S) and Emerging Sources Citation Index (ESCI) databases within the WoS are not included in this study.

In our analysis we focus exclusively on European research institutions, in an attempt to maintain some degree of organizational similarity in the style of governance. This is under the assumption that within the EU, research organizations adhere to a similar structure compared to research organizations in other countries**.** Additionally, we filtered the list of European Research Organizations, isolating the 'parent' institutions in these webs, defined as the most central nodes in the structure of umbrella organizations; those that lie at the top of their organizational hierarchies. We then attributed all the publications of the 'child' organizations to their respective parent organizations. The advantage of this parent/child system is twofold: a simplification of the previously chaotic network benefits the analysis. Additionally, this resolves an underlying source of error inherent to this type of data. Namely, publications are occasionally incorrectly attributed to their parent institutes. The limitation of this dichotomy is that we lose information about the nuances of the child institutes, as all of their publications are attributed to the parents. As a result of applying all the mentioned filters, a total of 643 institutions were selected.

Afterwards, we calculated three bibliometric indicators, only taking publications and reviews into account, between the years 2009 – 2016. The analysis implements bibliometric indicators related to scientific impact and two types collaboration; with international actors and the association with the industry sector. The chosen indicators are all size-independent: **PPtop5%** (citation impact indicator): The proportion of a research organization's publications that, compared with other publications in the same field and in the same year, belong to the top 5% most frequently cited. **PP(Int_collab)** (Collaboration Indicator): Proportion of international collaborative publications. This means the proportion of a research organization's publication that has been co-authored by two or more countries. **PP(Industry)** (Collaboration Indicator):

The proportion of a research organization's publication that have been co-authored with one or more industrial organizations. All private sector, for profit business enterprises, covering all manufacturing and services sector, are regarded as industrial organizations.

We used K-Means clustering to cluster our data, set the number of clusters to 3 and used the Z-score of the parameters. Z-score assumes a normal distribution, so we visually inspected the distribution of the parameters. Two of our parameters had a non-normal distribution: **PP(Industry)** and **PPtop5%**. We have these parameters normally distributed by transforming **PP(Industry)** into logarithm of **PP(Industry)** with base 2 (**log_Industry**) and **PPtop5%** into square root of **PPtop5%** (**sqrt_top5)**. Therefore, we made the K-Means with the Z-score of **PP(Int_collab)**, **log_Industry** and **sqrt_top5**. We made the decision tree in order to facilitate the further interpretation of our clusters, by fitting a decision tree to the data points with deep 2 and the Gini Impurity as split criteria.

Results and preliminary conclusions

Through the K-means clusters, we observe the International collaboration variables as being the best predictor to create the clusters (Figure 2). This is supported with the information provided by the decision tree (Figure 3) which shows this variable at the top the tree to discriminate the first two nodes leading to the different clusters, where the decision rule set the range of values as ≤ 0.592.

In the Figure 2 one can observe there is a correlation between both variables, where an increase of collaboration with ROs from abroad is related to an increment in the scientific impact. This varies for specific institutions in the sample. These results are in line with many bibliometric studies carried out by CWTS (AKA, 2015; NWO-WOTRO, 2017). Conversely, it seems there is no direct correlation between the variables, International collaboration and Industry ties. Literature suggest as one of the motivations for internationalization having access to new markets. This allows a diversification of resources that may expand the economic revenue for the Organizations and avoid to rely solely on national funding sources (Zacharewicz *et al.*, 2017).

From the clustering results (Figure 2) we can notice that despite the differentiation of the sample in tree clusters, the tree groups of organizations share characteristics, this is clearer for the impact indicator (PPtop5%). In the other hand, it is possible to identify a small group of organizations performing as outliers, specifically for clusters 2 and 3. In general terms, these clusters have the same response for the Industry indicator showing two well defined groups, with the vast majority of the organizations scoring low values (94% values between 0 - 0,2) and a minuscule portion where almost all the publications are shared with the private sector. When analysing the organizations belonging to this small group, it is possible to identify Research Technological Organizations (RTO), considered as performing in the semi-public sector and with tights links to firms. It is worth to note that, the high percentage of ROs scoring low values, may also indicate that, when assessing research collaboration through the **PP(Industry),** this metric may not reflect the engagement of ROs with the private sector and perhaps other forms of collaboration among institutions, rather than publishing, are being developed, such as informal exchange or patents creation.

Organizations performing with high scores for International collaboration and scientific impact were represented for different ROs profiles, including MOCs, IRIs and RTOs. Regarding OECD (2011) IRIs are in many cases highly innovative in organisational terms and some of them have outstanding performances.

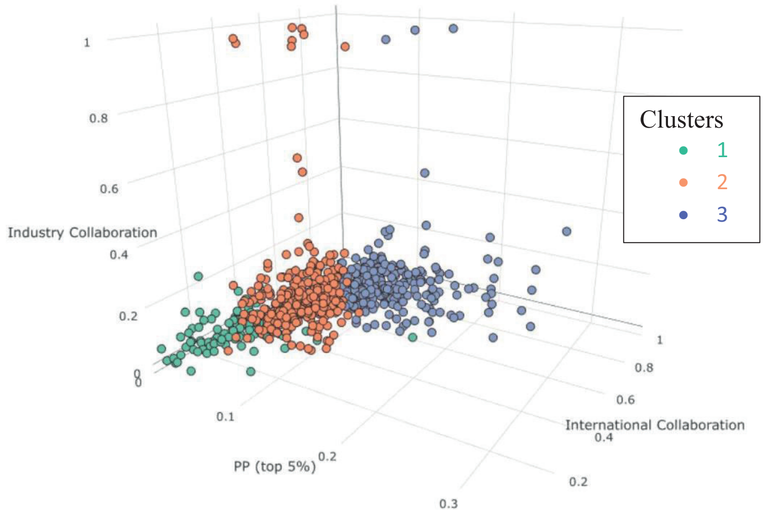

Figure 2. Scatter plot representing K-means output for a 3 dimensional space. The dots represent Research Organizations and the colours are clusters.

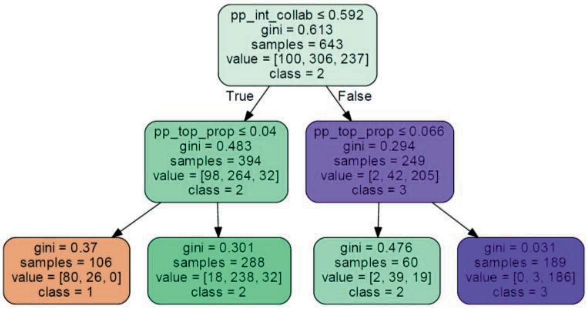

Figure 3. Decision tree output from K-means cluster model.
The top 3 nodes are decision nodes. The bottom 4 nodes are end nodes. The first row in a decision node is the logic test of the node. If true, go left, if false, go right. The second row is the Gini impurity of the node. The third row is the number of samples in each node. The fourth row is the number of samples from each class in the row (class 1, 2 and 3, respectively). The fifth row is the class predicted by the node. The colours represent the predicted class in the node, red is class 1, green is class 2 and purple is class 3. The intensity of the colours represents the relative frequency of that class in the node.

While our analysis does show that there are observable differences between each cluster of ROs, there were some limiting factors to our analysis. As previously mentioned, measuring industry collaboration is not straightforward due to the nature of these collaborations. We include collaborations that are based on accessible bibliometric information, however the true scope of industry collaboration may well exceed what is presently reported.

This article is a work-in-progress, and presents a preliminary exploration of the structures which underlie Research Organizations. More in-depth research is needed before we can make strong claims about the different types of ROs.

Tracking content updates in Scopus (2011-2018): a quantitative analysis of journals per subject category and subject categories per journal

Frederique Bordignon[1]

[1] *frederique.bordignon@enpc.fr*
Ecole des Ponts ParisTech, Direction de la Documentation, Champs-sur-Marne, France

Abstract

The aim of this study is to track Scopus content updates since 2011 and more particularly the distribution of journals into subject areas. An unprecedented corpus of data related to sources indexed in Scopus has been created and analyzed. Data shows important fluctuations regarding the number of journals per category and the number of categories assigned to journals. Those variations are very irregular, invisible to the average user and unpredictable over time. They question the reliability of studies based on Scopus data if no precautions are taken. The suggestion is made that category changes should not systematically be applied to all previously indexed publications of a journal, but only to those that will be indexed in Scopus after the new assignment is made.

Introduction

As far as scholarly literature is concerned, two levels of aggregation can be used to delimit scientific areas: the article level and the journal level. Both journals and articles can be classified into fixed sets of subject areas but the delineation of journals at the disciplinary level plays a major role in scientometrics, mainly for analyses based upon the extraction of scientific outputs from databases. That is why those information and reference sources need to be organized through an appropriate and consistent classification scheme (Gómez-Núñez, Batagelj, Vargas-Quesada, Moya-Anegón, & Chinchilla-Rodríguez, 2014). It serves as the basis of profiling authors, research groups, institutions or countries and helps in the making of comparisons and rankings. It is also useful in the calculation of standards for relative citation indicators. And beyond those research evaluation perspectives, journal classifications can also be used in describing the structure of scholarly publication and designing maps of science.

The two following tenets were formulated a long time ago: comparisons should be made in terms of "like with like" (Martin & Irvine, 1983) and over time in terms of fixed journal sets (Narin, 1976). But bibliographic databases do not take these principles into account and the data that is made available is used unsuspectingly by analysts in organizations.

The aim of this study is to track Scopus coverage updates since 2011 and more particularly the distribution of journals into subject areas. Scopus classification of documents is based upon the All Science Journal Classification (ASJC) whose structure does not evolve over time whereas the content of the different categories fluctuates substantially.

Background

Classification for evaluation purposes

(Archambault et al., 2011) stated that no international standard classification scheme exists that supports bibliometric research, and no single classification scheme has been widely adopted by the bibliometric community. Even research funders don't have a standardized classification

system to assess the impact of the funds distributed across different scientific fields (Katz & Hicks, 1995).
Among many initiatives to elaborate efficient classification systems for evaluation purposes, we can mention the following:

- the Steunpunt Onderwijs & Onderzoek Indicatoren (SOOI) implemented for the evaluation unit in Leuven (Glänzel & Schubert, 2003),
- the CHI Research classification (from Computer Horizons Inc) designed for the US National Science Foundation (NSF) (Carpenter & Narin, 1973) and also used by the Canadian Observatoire des sciences et des technologies (OST)
- the Australian Research Council Evaluation of Research Excellence (ERA) classification, abandoned since 2012.

However, it seems that the two most commonly used systems are those on which the Web of Science and Scopus databases are built.

The number and more particularly the diversity of classification schemes complicate comparative analyses (Gómez, Bordons, Fernández, & Méndez, 1996) because of the dual problem of matching categories and delineating journals comparable sets.

Mono vs multi-disciplinary classification systems

Some systems provide a way to classify publications with a great level of details in a restricted research area: for instance the widely used JEL (Journal of Economic Literature) classification system in economics, the Chemical abstracts service in chemistry or the MeSH (Medical Subject Headings) hierarchical system in medicine.
On the opposite, others are appended to multidisciplinary databases that index articles from journals and offer the possibility to retrieve them according to the field(s) the journals are assigned to. Journal level classification systems are of course very convenient but they are known as well to be sometimes too fuzzy, at least not so accurate as article level classifications. Indeed it is well known that most journals contain articles dealing with a relatively broad range of themes, in spite of their "main subject". Thus, a subject delimitation based on journal classification will probably contains some articles weakly related with the target subject, while some pertinent articles will be missing (Bensman, 2001; Gómez et al., 1996). And (Pudovkin & Garfield, 2002) said about the Web of Science classification system that "journals are assigned to categories by subjective, heuristic methods. In many fields these categories are sufficient but in many areas of research these ‘classifications’ are crude and do not permit the user to quickly learn which journals are most closely related."

Multiaffectation classification systems

Another limit of journal level classifications is due to the fact that many journals are assigned to multiple categories to better represent the scientific themes their articles deal with. A mutually exclusive classification is of course more convenient, in particular because it prevents a journal to being counted more than once. What is more, those classifications are generally not well documented (Archambault et al., 2011), and therefore there is no indication about why one or more categories were chosen for a particular journal. (Wang & Waltman, 2016) found that a significant share of the journals in both databases, but especially in Scopus, seem to have assignments to too many categories and then suggested to adopt a stricter policy supported by the use of citation analysis when assigning journals to categories.

Multiaffectation is supposed to reflect interdisciplinarity but in the end, multidisciplinary journals (eg: *Nature*, *PNAS*, and *Science*) are the most poorly managed and that is what leads (Wang & Waltman, 2016) to reconsider journal classification systems at a more fundamental level and warn an increasing share of publications cannot be properly classified at the journal level because of the increasing popularity of large multidisciplinary journals (eg: *PLoS ONE*). Scopus allows the assignment of a journal to several ASJC categories.

Stability over time

Exploring the limits of existing classification schemes and trying to improve them has given rise to many studies in the field of bibliometrics and scientometrics. But among them, the problem of the changes over time has more rarely been tackled and assessed. At least, the problem of fitting new journals into existing schemes has been dealt with: (Leydesdorff, 2002) with the idea of comparing structural changes in a database with reorganizations of relations among previously included journals concludes that "if one does not systematically account for redelineation in the groupings over time but uses "fixed journal sets" instead, one risks making a prediction of performance with reference to an outdated unit.". Despite this conclusion, Scopus (more particularly the possibility to request for Scopus data according to preset corpus of journals in different subject areas) is still the easiest way to retrieve data to produce reports in many organizations.

The question is whether these analyses are reliable when they cover different periods of times and subject areas if the different sets of journals are not stable and if the changes are not clearly reported. Indeed, queries in Scopus do not take into account any journal assignation update according to the publication year the query is based upon.

In this study, we investigate 2 kinds of potential changes in Scopus: (1) number of journals per categories (2) number of categories per journal, both impacting the delineation of categories and therefore the data retrieved from Scopus.

Methods

The All Science Journal Classification scheme

Scopus journal classification system is called the All Science Journal Classification (ASJC). There seems to be no official description about the way it is constructed. It has always been freely available online either from a dedicated page on the Elsevier website and an Excel file available for download, or from the former JournalMetrics website. It can also been downloaded from Scopus database (*Browse sources* page).

It is commonly described as consisting of two levels, but there is actually a third level above all, differently called Top-Levels, Supergroups or Subject areas (depending on time periods and downloadable files). This uppest level is not used at all in Scopus but can be used to filter out journals in the Excel file. The lowest level has 307 subfields, and the intermediate level includes 26 fields called *Subject areas* in Scopus. There is another field and another subfield for the *Multidisciplinary* category. All the subfields are assigned a 4-digit code.

We do not know how the assignment of journals to fields and subfields is decided but we can infer it is done by the Scopus Content Selection and Advisory Board, "an international group of scientists, researchers and librarians who represent the major scientific disciplines" (Elsevier website, 2019[1]).

Table 1. ASJC journal classification system

Supergroups	***Fields***	***No. of Subfields***
-	Multidisciplinary	1
Health Sciences	Medicine	48
Health Sciences	Nursing	23
Health Sciences	Veterinary	4
Health Sciences	Dentistry	6
Health Sciences	Health Professions	16
Life Sciences	Agricultural and Biological Sciences	11
Life Sciences	Biochemistry, Genetics and Molecular Biology	15
Life Sciences	Immunology and Microbiology	6
Life Sciences	Neuroscience	9
Life Sciences	Pharmacology, Toxicology and Pharmaceutics	5
Physical Sciences	Chemical Engineering	8
Physical Sciences	Chemistry	7
Physical Sciences	Computer Science	12
Physical Sciences	Earth and Planetary Sciences	13
Physical Sciences	Energy	5
Physical Sciences	Engineering	16
Physical Sciences	Environmental Science	12
Physical Sciences	Materials Science	8
Physical Sciences	Mathematics	14
Physical Sciences	Physics and Astronomy	10
Social Sciences	Arts and Humanities	13
Social Sciences	Business, Management and Accounting	10
Social Sciences	Decision Sciences	4
Social Sciences	Economics, Econometrics and Finance	3
Social Sciences	Psychology	7
Social Sciences	Social Sciences	22
4 supergroups	**26 fields**	**307 subfields**

The *Multidisciplinary* field and its unique subfield is dedicated to journals with a very broad multidisciplinary scope like *Nature*, *Science* or *Scientific reports.*

In all fields, there are 2 quite similar subfields:

- one whose label starts with the "*General*" mention and code ends with 00,
- the other whose label ends with the "*(miscellaneous)*" mention and code ends with 01.

It is impossible to say what led the Scopus experts panel to choose between the *General* subfield or the *Miscellaneous* corresponding subfield. There are many examples of journals assigned to both (for example, *Biology Letters*, assigned to the "*General Agricultural and Biological Sciences*" subfield and the "*Agricultural and Biological Sciences (miscellaneous)*" subfield.

Like other classification schemes, the ASJC has been criticized, most frequently because of confusing subfield labels (*Linguistics & Language* and *Language & Linguistics*, (Wang & Waltman, 2016)) or strong imbalanced distribution of journals and therefore documents among

[1] https://www.elsevier.com/solutions/scopus/how-scopus-works/content#content-policy-and-selection, available online on February 2019

the fields (Jacsó, 2013). There have been attempts to improve it (Gómez-Núñez et al., 2014; Jacsó, 2013) but still few considerations about the impact of coverage changes over time.

The nomenclature structure itself is stable since 2011, no new field or subfield has been created over the period we are interested in. Codes remained the same and names of fields and subfields as well, excepted for the *General* field which changed name in 2016 and was renamed *Multidisciplinary* and all the subfields ending with the "*(all)*" mention (eg: *Agricultural and Biological Sciences (all))* that changed name and have been started with "*General*" since 2017 (eg: *General Agricultural and Biological Sciences*).

Data

We retrieved all the title list files Elsevier has released twice a year since 2011 to investigate what content is included in Scopus. Journals, trade journals, conferences and book series are listed but we only focus on journals in this study. Most of those files are still available online thanks to the Wayback machine website. They are the best way to retrieve the metadata needed to our study. We only kept one file a year (the one published at the end of each year) and compiled the 8 files into a single dataset. The aggregated data (Bordignon, 2019) used for this study is available for reuse and further investigation (SNIP values and Open Access status are included in the dataset even if they are not analyzed in our study).

Results

Inclusion and withdrawal of journals at the category level

Table 2. Number of journals included in Scopus and annual growth

	2011	2012	2013	2014	2015	2016	2017	2018
No. of journals	28 335	29 561	31 154	32 332	33 058	33 810	34 772	36 189
Annual growth	-	+4,3%	+5,4%	+3,8%	+2,2%	+2,3%	+2,8%	+4,1%

As far as Scopus content is concerned, the most significant change since 2011 is the increasing number of journals indexed in the database (+28% between 2011 and 2018, with most important increases in 2012 (+4,3%) and 2013 (+5,4%)). Very few journals are merely dropped (min=27;max=318). And even inactive journals are sometimes added to the index (inactive either because they changed name, merged with another journal, splitted or simply ceased to publish anything).

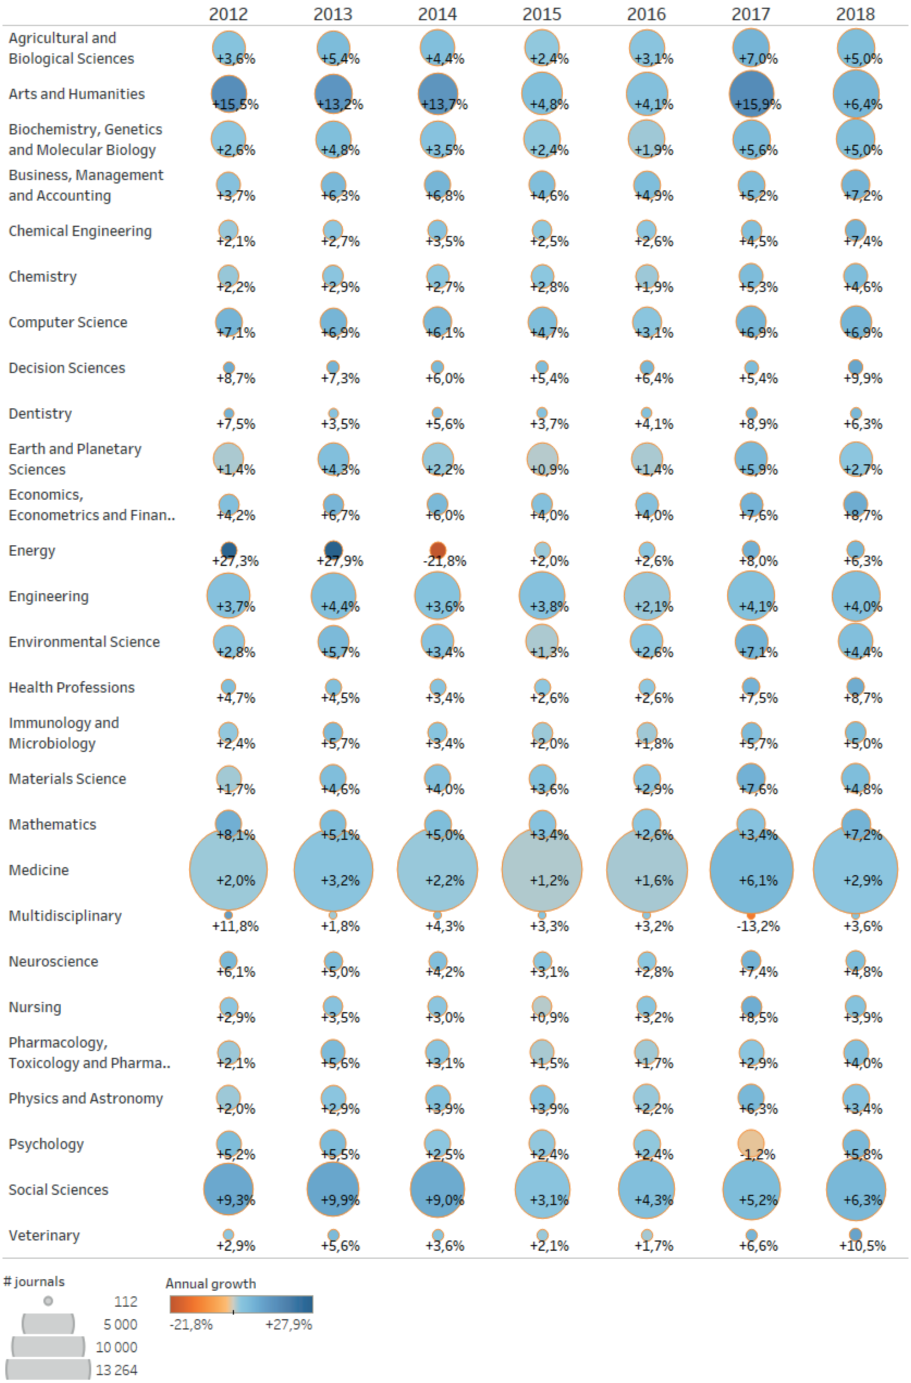

Figure 1. Number of journals per field and annual growth

The evolution of the number of journals is contrasted from one field to another. Here are the highlights Figure 1 reveals:

- in 2012, 2013 and 2014, among the largest fields (2000+ journals), the fields *Arts & humanities* and *Social sciences* had the highest increase (from 9% to 15.5% annual growth). Another large inclusion of sources also occurred in 2017 in *Arts & humanities* (+15.9%, ie: 506 journals added)
- in general, there has been no significant increase in any field in 2015 and 2016, with a maximum of +5.4% in 2015 and a maximum of +6.4% in 2016 (both concerning the *Decision sciences* field).
- in 2017, 500+ journals were added to the *Arts & humanities* field (+15,9%)
- few fields are undergoing decreases:
    - *Psychology* in 2017, -1.2% but this only represents 15 journals, 73 were finally added the following year
    - *Multidisciplinary* in 2017 also with -13.2%, but this amounts to only 17 dropped journals
    - the *Energy* field must be considered as a particular case: indeed it recorded both the highest increase and the highest decrease over the entire period, with the addition of 126 journals in 2013 and the same amount of sources withdrawn the year after. Out of the 126 journals added in 2013, 91 were removed from Scopus in 2014 (all belonging to the *General Energy* subfield).

These updates are unpredictable and have inevitably an impact on comparative studies that are conducted on those fields at different periods of time.

Apart from these fluctuations (mainly additions) in the number of journals per field, it is important to know whether these additions are newly included journals or whether they "come from" other fields, in other words whether journals would change field/subfield, be assigned to more fields/subfields or withdrawn from any field/subfield.

Table 3. Annual percentage of journals whose assignment to fields and subfields has been updated

2012		2013		2014		2015		2016		2017		2018	
subfield	field	subfield	field	subfield	field	subfield	field	subfield	field	subfield	field	subfield	field
0,1%	0,1%	0,2%	0,2%	1,0%	1,0%	0,5%	0,5%	0,3%	0,3%	**10,6%**	**6,9%**	1,5%	1,0%

Table 3 clearly shows that field or subfield shifts are very unusual. This means that a journal is only very rarely reassigned to more or less fields/subfields. The changes mentioned above are therefore only due to additions or withdrawals of journals from the Scopus index. However, a significant change can be observed between 2016 and 2017; Table 4 focuses on this time period and shows that, apart from the *Multidisciplinary* field (and only 33 sources involved), the field for which most shifts are detected is *Psychology* with a significant share (21.6%) being reassigned to more or less subfields.

Table 4. Number and percentage of journals per field with subfield shifts between 2016 and 2017

Fields	No. of journals with subfield shifts	% of all journals in the field
Multidisciplinary	33	25,60%
Psychology	274	21,6%
Immunology and Microbiology	132	18,0%
Biochemistry, Genetics and Molecular Biology	439	17,7%
Health Professions	85	17,7%
Pharmacology, Toxicology and Pharmaceutics	172	16,3%
Neuroscience	99	15,9%
Veterinary	33	13,60%
Medicine	1630	13,4%
Nursing	88	12,5%
Environmental Science	239	12,1%
Social Sciences	652	11,2%
Engineering	376	9,5%
Computer Science	136	8,7%
Earth and Planetary Sciences	149	8,1%
Agricultural and Biological Sciences	186	8,0%
Arts and Humanities	201	6,3%

The Scopus search interface does not allow to query or filter on subfields. But skilled analysts who use the source list file can do this sorting after having exported the bibliographic data; their comparative analyses are likely to be biased because of too important changes between 2016 and 2017.
In addition, some world university rankings by subject are based on citation indicators collected across several subfields. The results of these rankings are necessarily skewed by these significant updates in Scopus.

Number of categories per journal

Our 2018 data shows that the maximum number of fields assigned to a journal is 9 (*The Bulletin of mathematical biophysics*) whereas the highest number of subfields is 13, assigned to *Journal of Geophysical Research*. This example reveals several technical problems actually: first of all, this journal is organized in 7 disciplinary sections (eg: *JGR: Atmospheres*, *JGR: Biogeosciences* etc.). Those sections are not integrated into the Elsevier title list, this might be the reason why so many subfields are assigned to this source. On the other hand, when querying Scopus sources index about *Journal of Geophysical Research,* there are 2 answers: one for the *stem* journal without any mention of sections, the other for a single specific section (*Solid Earth*). And finally, when searching for any documents with *Journal of Geophysical Research* as source title, relevant results indicate the complete correct titles of all the discipline sections. Even if further investigation is needed to measure the extent of the issue, it seems that the 3 sources of information about Scopus content are not consistent.

As far as our dataset is concerned, unsurprisingly, it shows an increasing average number of fields (+1,49% since 2011) and subfields (+3,11% since 2011) assigned to journals, which seems to attest the increasing interdisciplinarity of science (Morillo, Bordons, & Gómez, 2003). Our calculation of the average number of fields assigned to journals is consistent with (Wang & Waltman, 2016) results (2.1 in Scopus) as shown in Table 5.

But consistently with what we stated earlier, this increase is not due to updates at the journal level but almost exclusively due to the addition of journals to the database index. Since 2013, those newly included sources have always been assigned to more fields and subfields on average than those previously indexed.

Table 5. Average number of fields and subfields per journal for added or previously included ones

		2011	2012	2013	2014	2015	2016	2017	2018
Avg number of fields	Added	1,48	1,51	1,56	1,57	1,61	1,66	1,67	1,66
	Previously included	1,53	1,53	1,53	1,53	1,53	1,54	1,54	1,54
Avg number of subfields	Added	1,91	2	2,02	2,08	2,26	2,37	2,45	2,38
	Previously included	1,99	1,98	1,98	1,99	2	2,01	2,01	2,03

This is a global tendency and further studies will be able to reveal differences among fields. It should also been worth checking whether newly created journals (and not newly included ones) are being assigned more fields and subfields as well.
It seems unlikely that interdisciplinarity will only arise on newly added journals. This means that the journals already in the database should be re-examined by the Elsevier experts panel. And of course this reinforces the idea that indexing at the article level better reflects reality.

Discussions and perspectives

Whether analysts work directly in Scopus or use the data Elsevier makes available in downloadable files, they cannot perform the time-consuming analysis work that would assess if updates to Scopus coverage are not too substantial and if comparing reports produced from one year to the next is still possible.

Moreover, the large volume changes we have highlighted in some categories certainly do not reflect the scientific reality of the field but rather Elsevier's objectives to increase its coverage. And yet, the consequences can be significant: for example, on SNIP values due to an unstable scope of journals and therefore a very unstable citations rate, or on international thematic university rankings whose evaluation criteria are based partly on the collection of citations and outputs according to subject areas.

Without giving up the extension of the coverage and the necessary updating of the database, Elsevier should inform the user of Scopus content updates in order to prevent potential impacts on the resulting analyses. This is obviously something very complex to set up in the interface, but one cannot assume that all users regularly consult the title list file. One possibility is to reflect category changes of a journal only on newly added publications (recently published or not) and not on all publications already present in the database. It will mitigate the bias for university rankings or the calculation of indicators.

As for the increase in the average number of fields and subfields per journal, since it is limited to additions, it cannot be said that it can be used to support work on interdisciplinarity.
On this particular point, it should be reiterated that a journal can be added to the list of indexed sources even if it has a long-established history, or even if it is inactive. Therefore, there is a

limit to our analysis since we would have to examine whether the increase in the average number of fields/subfields per journal is true for all journals added to the index or more particularly for those created and included at the same period of time.

Conclusion

We know that classifications at the article level are more relevant, but since bibliographic databases offer the possibility of queries, analyses and data exports based on the classification of journals, it is important to know to what extent this could impact their reliability for bibliometric analyses.

We revealed the existence of very important updates in the Scopus database which can have a significant impact, depending on the scope of the analyses carried out. We also showed that these fluctuations were very irregular, invisible to the average user and unpredictable. That is why we suggested that category changes should not systematically be applied to all previously indexed publications of a journal, but only to those that will be indexed in Scopus after the new assignment is made.

Abstract

The 3D printing is an emerging technology whose principle is to deposit material in thin layers until the piece takes on the projected shape. 3D printing has the potential to change society as well as some scientific fields. Hence, considering this last aspect, the present paper aims to map the most prevalent research areas in 3D printing domain during the 1983-2017 period analyzed. A total of 119,800 documents on 3D printing were collected from Web of Science and Scopus. Results show that the number of documents on 3D printing increased 13.65%, when considering Scopus and Web of Science together. The areas with the highest ratio of 3D printing documents are engineering, computing and materials science. The analysis of keywords co-occurrence and field trends of magazines and conferences revealed also a close linkage between 3D printing and health sciences, where the concepts of bio-ink, bioprint and bioplotter are introduced. These results reinforce the role of 3D printing as a research domain that is been structured upon different areas.

Introduction

Emerging technologies have the potential to create a new sector or to transform an existing sector; they may be also considered as discontinuous technologies derived from radical innovations or by the convergence of previously separated research chains (Day, Schoemaker & Gunther, 2009). An example of this type of technology is the 3D printers, whose first patents were granted in the middle of 1980's.

The 3D printing technology is based in the additive manufacturing process, since it works under the principle of material deposition in thin transverse layers until the designed shape is acquired. It differs from the conventional additive manufacture that is grounded in the subtractive process and the material removal from the block to be formed, which requires a variety of specific tools and equipment. Comparing the additive and the subtractive manufacturing, in the second we have a longer time production as well as a higher energy and material consumption and a higher amount of waste and pollutants generated.

According to Berman (2012), the usage of 3D printing is divided into three phases: in the first, its greater use aims at the construction of prototypes or models; in the second phase, its use aims at the creation of products for marketing test, with variations of size, styles, and colors. This phase is also known as direct digital manufacturing or rapid tooling. In the third phase, the main use is made by final consumers, who may have their individual printers and, instead of buying a trade product, they can purchase the product file and print it by their own. The progress to the third phase depends on the ease of software execution for developing each part, as well as the cheapening of inputs and equipment.

It is noteworthy highlight the economic impact of 3D printing, estimated to be between US $ 230 billion and US $ 550 billion per year by 2020, which would have a higher influence on the final consumer, i.e. finished products that are cost-effective compared to the acquisition in retail (Manyika et al, 2013).

Since its development, 3D printing has been considered a technology with a high potential to change the world around us. Rifkin (2012) and many authors believe that it is responsible for the 4th industrial revolution. For other authors (Prince, 2014, Garrett, 2014, Gleber, Uiterkamp & Visser, 2014), 3D printing is about to bring a radical change in contemporary culture due to the advance in manufacturing products applied to industry, art, medicine and domestic environment. Also, they believe it has the power to provoke changes in the world economy by changing business models, production sites and supply chains as well as promoting changes in work structures.

The impact of 3D printing is already perceived in our society through a range of products, including parts to build a house or components to assemble cars and airplanes. Through this technology it is also possible to produce clothes and accessories, household utensils, food and medicines. More recently, we witnessed products coming from 3D printing that may represent a paradigmatic chance in society: the impression of skin, bone, vascular grafts, tracheal splints, cardiac tissue, cartilaginous structures, models of molecules for research (Murphy, Atala, 2014). Such products and others not yet available have the potential to change the form and time of medical treatments. In fact, the application of 3D printing in solving issues in regenerative medicine will represent its most disruptive use (the one that causes interruption of the regular course of a process), being the impression of organs its main challenge.

Taking into account the current (and the future) uses of 3D printing in generating products that impact different areas and social sectors, we decided to investigate whether this technology figures out a domain, in the sense of Hjorland & Albrechtsen (1995). Hence, considering 3D printing as a scientific domain, in which their actors share thoughts, discourses and communication forms, among other aspects, we are interested, in this paper, to map the most prevalent research areas in this domain. Although the technology dates back to the 1980s, to our knowledge, there is no similar study within the scientometric or bibliometric literature. We understand, therefore, that this is a pioneering study, in which the mapping of the most prolific areas on 3D printing along the last decades will allow us to better understanding how research is been developed in this domain.

Materials and Methods

The search strategy included three main steps. The first search strategy contained a couple of words found in articles and news about 3D printing plus some synonyms listed in MESH terms and their variations. Then, based in the results of the first strategy, a co-occurrence analysis of keywords was performed, which allowed to identify some other words and uses of 3D printing techniques applied to specific areas that started to have a proper term as, for example, bioprinting. Finally, words and their variations regarding the seven additive manufacturing families listed in ISO / ASTM 52900: 2015, or formerly ASTMF2792 (Standard, A.S.T.M., 2012) were added to the search. The final search strategy presented 49 word or expressions for 3D printing, as following: "Material Extrusion" OR "Fused Deposition Model*" OR "Fused Filament Fabricat*" OR "Directed Energy Deposit*" OR "Laser Engineer*" OR "Net Shap*" OR "Digital Light Process*" OR "Continuous Liquid Interface Production" OR "Continuous Digital-Light Process*" OR "Selective Laser Sintering" OR "3d print*" OR "threedimensional print*" OR "three dimensional print*" OR "3 dimensional print*" OR "Fast Prototyp*" OR "Solid Free Form" OR "Solid Freeform" OR "Rapid Prototyp*" OR "Additive Manufacturing" OR "VAT

Photopolymerisation" OR "Stereolithography" OR "ExOne" OR "Powder Bed Fusion" OR "Direct Metal Laser Sinter*" OR "Selective Laser melt*" OR "Electron Beam Melt*" OR "Material Jet*" OR "Multi-Jet Fus*" OR "Binder Jet*" OR "Ultrasonic Additive Manufactur*" OR "Voxeljet" OR "Drop On Demand" OR "Nano Particle Jet*" OR "Polyjet"

OR "Sheet Laminat*" OR "Laminat* Object Manufactur*" OR "Selective Deposit* Laminat*" OR "Electron Beam Additive Manufactur*" OR "Laser Metal Deposit*" OR

"Direct Metal Deposit*" OR "prototyping" OR "bioplot*" OR "bioprint*" OR "bio-print*". The detail of this process is the focus of a scientific article in development.

The data on the scientific production in 3D printing were retrieved from the two leading scientific bases: Web of Science (WoS) and Scopus. An update search was carry on January 21st and 22nd of 2019.

A total of 88,571 documents were retrieved from Scopus and 50,074 documents from WoS. The documents of both databases were joined up using the R version 3.5.2 programming language (R Core Team, 2018) and the bibliometrix package, version 2.0.2 (Aria, Cuccurullo, 2017). To remove duplicities, we considered three criteria: title, journal name and year of publication. As can be seen in the Venn-Euler diagram (figure 1), the intersection between the Scopus and WoS documents was 18,845 documents; the duplications represent 13.89% of the sum of the documents of both databases. Once the duplicity was withdrawn, the union between Scopus and WoS summed of 119,800 documents.

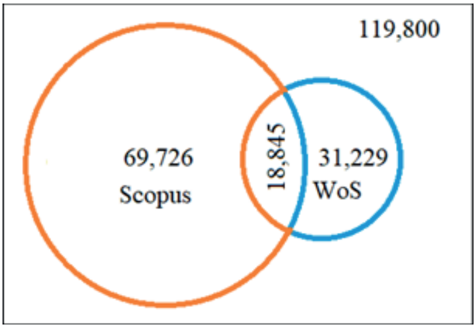

Figure 1. Venn-Euler diagram with the totals of documents on 3D printing retrieved from the databases Scopus and WoS.

The period analysis 1983 - 2017 was divided into seven quinquennia to visualize the evolution of the data studied, namely: 1983 - 1987, 1988 - 1992, 1993 - 1997, 1998 - 2002, 2003 - 2007, 2008 - 2012 and 2013 - 2017.

In order to evaluate if the growth on the topic 3D printing was significant, we compared it with the growth of the total number of documents indexed in each database throughout the studied period. Data on total number of documents in each database was obtained on April 07th of 2018.

We used VOSviewer software version 1.6.9 for elaborating graphs and the analysis of networks (van Eck, Waltman, 2009). For the co-occurrence network, we used all keywords listed in the 119,800 documents, but a cleanup was performed to remove nonsignificant terms (like 'na'). Cuts were performed by increasing the minimum number of occurrence of the word so that the network had a maximum of 1000 nodes, allowing visual analysis to be possible.

Due to the large number of data and analyzes as well as the limitation of space of the present paper, we chose to perform a cut in some analyzes selecting only the odd quinquennia.

For the calculation of the average growth rate in the period (35 years), we used the following equation:

$$\text{Growth Rate}= [((\text{valor final} / \text{start value})^{\wedge}1/\text{period}) - 1]*100 \qquad (1)$$

Results and Discussion

The results are presented in two groups. In the first, we evaluated the growth of scientific production on 3D printing, the countries responsible for these publications and the distribution towards the type of production. We understand that this first block of analyzes is necessary to better contextualize the following section, which is the focus of our study. In the second group of results, we present analyzes on keywords co-occurrence and trends of areas regarding journals and annals that allow us to identify the most prolific areas in 3D printing publications.

Growth, affiliation, and typology of scientific publications on 3D printer

The number of documents per period can be visualized in figure 2, where the total number of documents in both databases is represented by the bars, while the number of documents on 3D printing found in the two databases without duplicates (n = 119,800) is presented on the black line. For comparison, the figure also includes the annual totals of 3D documents at each database (Scopus - blue line; WoS - orange line).

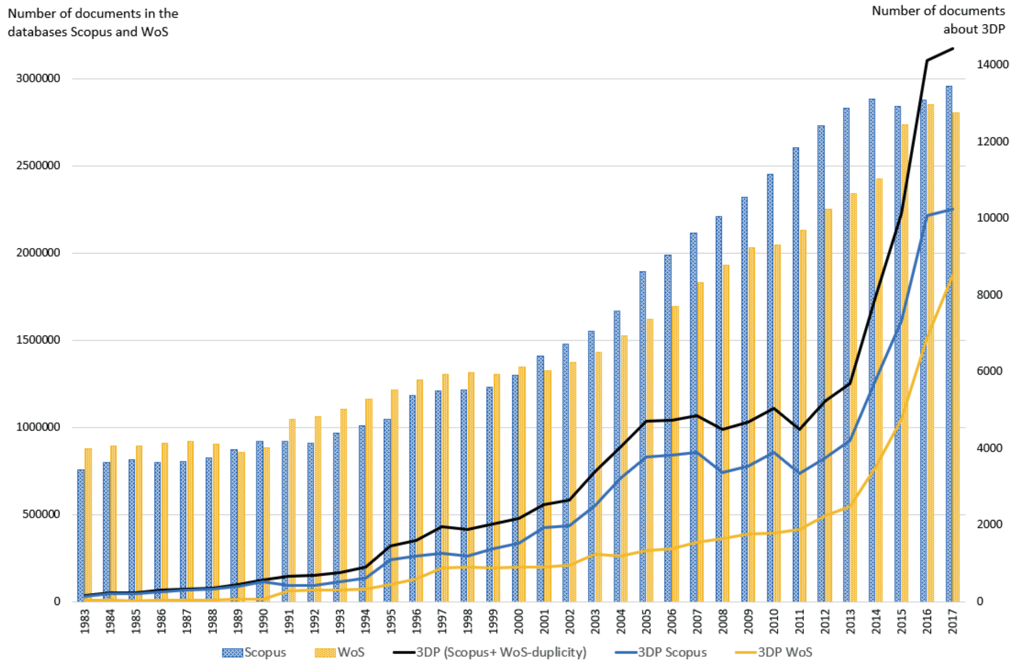

Figure 2. Number of total documents in Scopus and Web of Science (blue and yellow bars), number of 3D printing documents in each database (blue and yellow lines) and the sum of 3D printing in both databases without duplicity (black line), 1983-2017.

It can be noted a continuous and little-accentuated growth of total documents registered in the each database from 1983 to 2017 (blue and yellow bars). A different profile is observed for 3D printing documents (black line), which starts with a slow growth until 1993, but from this point onwards, there are three marked growth movements: one starts in 1994, another in 2002 and a last growth, where can be seen an explosion, that occurs by 2011.

The growth waves observed for the scientific production on this technology may have been influenced by events and initiatives that promoted and spread the concept of 3D printing, including: (a) the launch of the RepRap community in 2008, which began to teach, through free videos available on the internet, how to assemble a low-cost printer, which is the first open source 3D printer; (b) the foundation of the Thingiverse site, the first dedicated to file sharing for 3D printing using open source hardware (Michael et al, 2013); and (c) a patent breach in 2009 of the fused deposition modeling (FDM) technique, which allowed, in 2012, the launch of the first desktop printer. Afterwards, an explosion occurred in the manufacturing and supply of printers in the market using the FDM technique.

In order to evaluate the growth of the documents in 3D printing, we calculated the average growth rate in the period, as shown in table 1. The average growth rates of total documents are 3.98% and 3.39% in Scopus and in WoS, respectively. Documents on 3D printing displays an average growth of 13.07% and 18.00% in Scopus and in WoS, respectively. The sum of Scopus and WoS documents on 3D printing, withdrawn duplicity, presents an average growth rate of 13.65%, that is, more than three times higher than the growth observed for each database, indicating that 3D printing is emerging as a research domain.

Table 1. The average growth rate of the number of documents in the Scopus, WoS and of the sum of both databases on 3D printing documents in the period 1983-2017.

Source	Average growth rate in the period
Scopus	3.98%
3 DP Scopus	13.07%
Web of Science	3.39%
3 DP Web of Science	18.00%
3 DP (Scopus + WOS) - duplicity	13.65%

Once the previously results showed the number of 3D printing documents increased notably during the studied period, the document by type and by country of the authorship was analyzed in order to get evidences of how this domain are structured.

Figure 3 shows the total number of documents with single (blue) or multiple authorship (orange) by one of the 15 countries that contributed the most in four quinquennia. One first remark is that majority of documents are single authored, that is, the level of collaboration in 3D printing domain is very low.

As for the countries, it is clear the role of the United States that stands out in the number of publications in all quinquennia. In the last period, as evidenced, the country shows a lower performance. China, which did not appear in the period 1983-1987, appeared in the period 2003-2017 at second in the ranking position and remains in this position in the subsequent period with more than double documents as the previous period. Other Asiatic countries figured among the top-15 countries: Japan (in all periods), Korea and Singapore (since period 1993-1997) and Twain (since 2003-2007).

Two Latin American countries are included the ranking of top 15 countries with the highest number of documents on 3D printing are: Argentina, with a coauthored publication in the first period, and Brazil, which appeared in the 13th position (with 269 single authored documents) in the period 2003-2007 and in the 14th position (with 595 single authored documents) in the period 2013-2017.

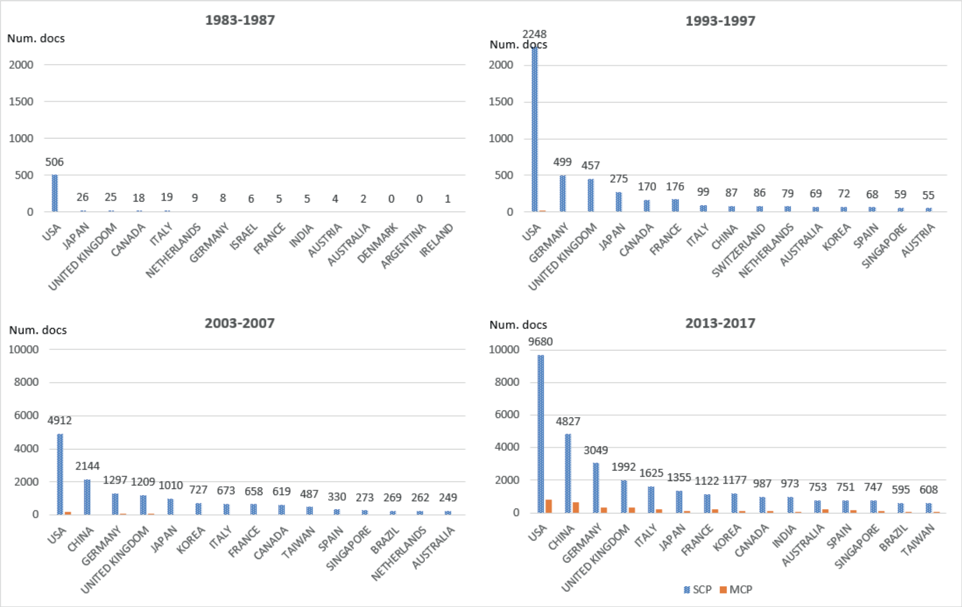

Figure 3. Number of documents on 3D printing retrieved from WoS and Scopus with single-authored (blue) or multiple-authored (orange), according to the author's country of affiliation, in different quinquennia.

In order to get a description of the communication forms of 3D printing domain, we The number documents by sources and by different types are shown in table 2. The distribution of documents by type is shown as a percentage of the total number of documents per quinquennium, whereas the classification in the ranking (right side) considers the total in the period.

It can be noted a remarkable increase in the number of sources in the period, with an average growth rate of 10.18%. We may consider the emergence of magazines on the 3D printing as well as magazines devoted to diffuse other types technological applications.

In table 2, we can also verify that the scientific article is the most frequent typology among documents on 3D printing. This typology presents the highest number in four of the six quinquennia, representing 43.21% of the total. The typology with the second highest frequency is conference paper, which represents 34.33% of the total and, for two consecutive periods, 2003-2007 and 2008-2012, it has the largest number of documents. It is well known that conference papers is the most common means of communication of some areas, such as engineering, since it brings more speed in the diffusion for the new knowledge or for the new technology, thus guaranteeing, in a more agile way, the priority of the discovery or invention.

Primary fields of scientific publications on 3D printer

In this section, we present two main analyzes, keyword co-occurrence and trends of areas regarding journals and annals, in order to find out the most prolific areas in 3D printing publications which will help revealing aspects of the domain identity.

From Table 2, it can be observed that 77.5% of documents are classified under the typology articles or conferences. In order to qualify the scope of these documents, we present in table 3 the 15 top journals and 15 top annals of conferences with the highest number per period. For this study, due to the space limitation, we only present the data referring to four quinquennia.

The percentage that these 15 journals and conferences represent in relation to the total in the period is given by the sum of the percentages in the period removed the fields without filling. This value is presented in the last line of each quinquennium, whose result for journals varies from 11.68% to 25.34%, while for conferences the value varies from 25.48% to 37.74%.

It is observed that journals from engineering remains in all quinquennia, whereas journals from physics in the first quinquennia only, journals from computer science in the first two and journals from materials science in the second and third. In the last period, for the first time, journals from health area appear among the top 15 journals, including Tissue Engineering, Biofabrication and Lab on the chip.

For conference proceedings, annals from computer science and engineering appear in all quinquennia, while annals from materials science in the first, third and fourth and from physics only in the second. In this type of publications, we do not observe the presence of annals from other areas, probably because of the nature of this type of communication, which, as it is well known, has much prestige in areas with a more technological approach and also in some fields of exact sciences and mathematics.

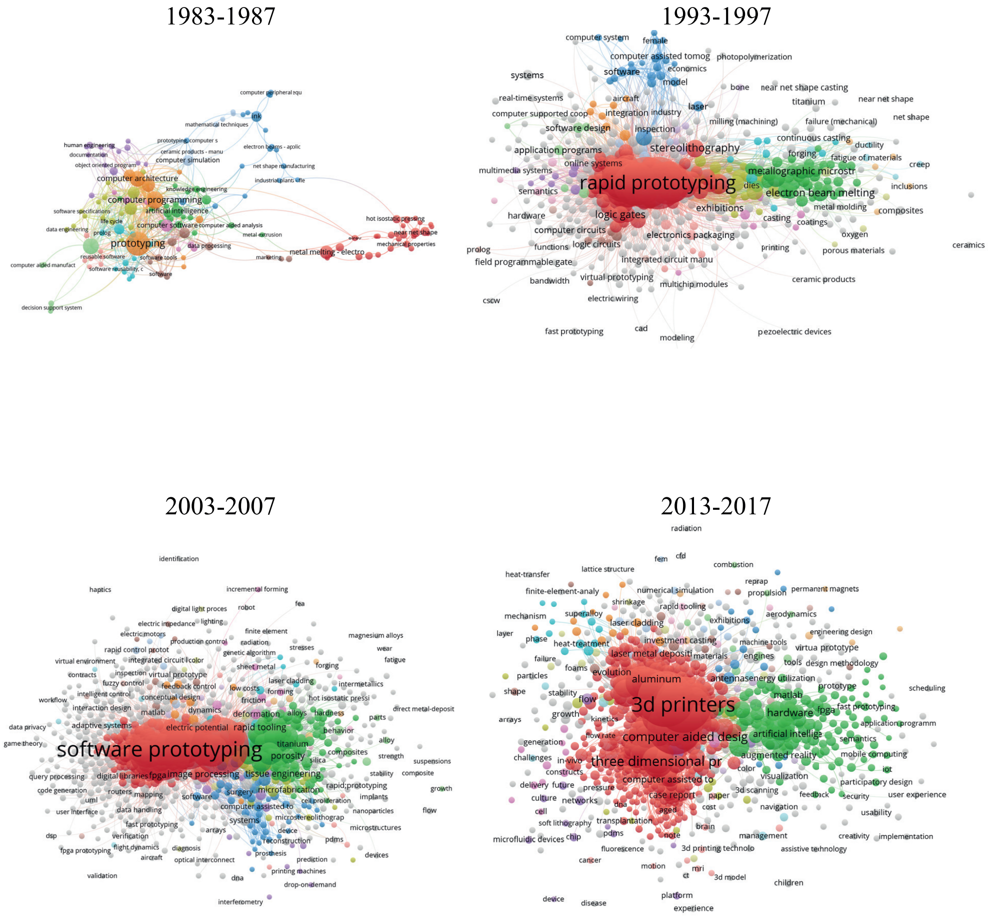
In order to better characterize the articles on 3D printing in terms of their priority areas, we performed a co-occurrence analysis based in all keywords presented in the 119,800 documents.

In Figure 4, it is possible to observe that the density of word networks increases from the first period to the last, as a result of the increase in the number of keywords with at least three occurrences (from 86 to 999) and the increase of connected items (from 151 to 989). It is also observed that the number of clusters grew very intensely up to the third quinquennium (from 12 to 225), but was reduced to 99 in the last period.



1983-1987

1993-1997

2003-2007

2013-2017

Figure 4. Keyword network of documents retrieved from WoS and Scopus on 3D printing per quinquennia.

The period 1983-1987 has 12 clusters; the largest cluster (red) displays 28 connected items that are clearly related to mechanical engineering. This cluster is shifted from the center of the network and is weakly connected to it. In the orange cluster, the "prototyping" node is the most co-occurring one within the network, a concept that gains prominence over time. If we isolate this node, we see a large number of connections between keywords related to computation, a central characteristic of the 3D printing technique, since it is necessary to use software for generation images and planning layers of decomposition of the material.

From period 1993-1997, the largest cluster (in red) assumes the central position, having the smallest distance between all elements of the network. In this quinquennium, there are 176 clusters, and the bulkiest cluster (red) has 109 items. Unlike the previous map, here the item of greater co-occurrence is "rapid prototyping". There appears to be an explosion of prototyping studies, printing techniques and also about computational part for designing the layers, which are now in the same cluster. It seems that the blue and red clusters of the previous period were combined and formed the green cluster, the second largest in this period. The composition of this cluster, points to issues related to engineering, physical and material science. The blue cluster refers to imaging techniques, and the element that links it to the central cluster is image processing.

The map of period 2003-2007 has 225 clusters, with a substantial number of small clusters. The largest cluster (red) maintains the characteristics of the previous period, being related to prototyping and computation. The cluster in green, the second largest in this period, has words related to 3D printing techniques such as stereolithography and lithography, biomaterials and tissue engineering, indicating an initial approximation with the area of health science.

Finally, the period 2013-2017 displays 99 clusters with 989 elements connected, the largest cluster (red) has 474 elements, which are mostly synonyms of the expression 3D printing. In this period, it appears, for the first time, some words as bioprint, bioplotter and bioink in the largest cluster. These new terms indicate a true approximation of 3D printing domain by the area of health science.

Conclusions

The 3D printing is an emerging technology with great potential to impact economy as well as to transform the routine of various social sectors. There is a high expectation that it will introduce many changes in society, including in the productive chain. In health, for example, the impression of organs may cause a revolution by impacting the productive chain of drugs, since the traditional treatment can be substituted by the implantation of a new organ printed in the 3D printer. It may also impact several scientific areas, once the printing of organs to treat diseases, research project related to these diseases may no longer be necessary or priority.

As we did not find studies in the field of Scientometric or Bibliometric regarding 3D printing, we decided to carry on this present study on the mapping of the most prevalent research areas at this domain. The design of this study may be considered extensive, since the volume of analyzed data included documents retrieved from a strategy search that used 44 terms. This strategy allows the development of future studies, with specific cuts to some of the topics identified, for example, aerospace identified in the conferences from 2003 to 2007, or health sciences evidenced in the period 2013-2017 and in the co-occurrence of keywords.

As main results, we noted a remarkable growth of 3D printing publications, which are mainly published in types of documents, articles and annals, which are totally compatible with the demand of this subject towards a fast flow of communication. As for the countries that have contributed more with this research domain, as expected, the United States appears in a prominent position, a result not only of its large tradition in research but also in patenting most of the 3D printing technologies. One positive and not expected finding was the contribution of Brazil, a developing and peripheral country in science with little tradition in technological development.

Regarding the areas, the data show that engineering, computer science and material science carry out most of the research on this technology, while health sciences has emerged in the last analyzed periods. Indeed, it was expected a closer relation between 3D printing and the areas of engineering, computer science and material science, since these are areas in which the technology is grounded. In other words: 3D printing is a equipment (engineering) that requires sophisticated software (computer science) and different inputs (materials science).

Due to the nature of the analyses presented in this study, we identified only the most prominent areas, but some other areas (with lower number of documents) may play significant roles for the establishment of 3D printing domain and must be understood through specific cuts. As a future perspective, we intend to look closer at some engineering specialties, in order to highlight other areas that may be masked by the large volume of material analyzed in this work. Another possibility is to investigate to the most prolific authors as well as their main works in order to identify where they are positioned in the history of the 3D printing domain development.

We believe that the enlargement of the analyses will make it possible to get a more comprehensive framework on the main areas, institutions and actors of 3D printing domain.

Acknowledgment

The authors are grateful to Pedro Accioly, founder of Maker Factory, for listing the significant events that helped increasing the use of 3D printing and to Gonzaga Sillas for aiding the R code that unified the two databases. Andreia Cristina Galina receives a PhD fellowship from Capes.

Abstract

Translational research (TR) aims to "translate" findings in fundamental research into the clinic, with the ultimate goal of better health outcomes. The term however is ambiguous and qualitative control tools have only been developed recently. They include identification and description of TR stages, as well as evolving from one stage to another. A proper evaluation of the TR in Her2 domain has not been performed thus far. Given the significance of the Her2 research and its implications into guidelines and pharmaceutical policies, we conducted a concise clustering of the pioneering publications of Dennis Slamon. Moreover we analyzed the keyword co-occurrence of the network extracted by the publications. By tracking the linkage strength within and between clusters, their dynamics and connected terms, we show how different TR stages occur and how they relate to each other. Our comprehensive mapping of the translational process of Her-2 research has implications for policy definition and implementation, as well as future TR evaluation framework

Introduction

Molas-Gallart et al. proposed a new framework for the evaluation of translational research (TR), suggesting to analyze how one TR stage is translated to another. In a medical context, TR aims to bring findings of fundamental research into medical and nursing practice, as well as needs from the clinic to the laboratory.

The application of this framework faces severe challenges, such as how to mark different phases of the translational process and how to chart the pathways along these phases. Small (2000) captioned clusters gathered together by citation links in a specific research area, then charted pathways between these clusters so that the discovery process could be logically followed. His approach was retrograde from existing discoveries back to the core, identifying paths that connect the clusters earlier. Cambrosio et al. (2006) mapped the emergence and development of translational cancer research. They found that journals or concepts on the same research levels such as basic research or clinical practice are more likely to cluster together via inter-citation networks and semantic network maps. These maps displayed links between concepts that co-occurred within the title and the abstract of a given article. Can the clusters of publications on a specific topic reflect different TR phases?

Her-2 is a gene located at the long arm of human chromosome 17. It was identified in the mid-1970s by transfection studies with DNA from chemically induced rat neuroglioblastomas by Shih, Padhy, Murray and Weinberg. Soon, the gene was found to be pro-oncogenic. Amplification or over-expression of the Her-2 gene occurs in approximately 15-30% of breast cancers, which thus were labeled "Her-2 positive" and was the most aggressive type before Herceptin was developed, approved by the FDA in 1998 and been used in the clinical practice ever since. The invention of this effective substance was based on what was called TR and represents one of the most prominent examples of bench to bed translations with an immense prognostic improvement for targeted patients.

In this investigation study, we use the concept of terms' co-occurrence in the publications on Her-2, an acronym for human epidermal (growth factor) receptor 2. Our goal was to using scientometrics tool to map the translational process of Her2 research. Some scientists compare the TR to crossing a valley of death, underlining the significant gap between basic science and clinical reality, as well as burden and barriers along the translation process, such as policies. Her2 research is of an uttermost significance, being implemented constantly into the clinic: patients' prognostic screening, therapy choice, pharmaceutical developments etc. we clustered the publications of the domain's pioneer, Dennis Slamon, and created co-occurrence keyword networks with cross-link comparison to reenact the translational processes, from the lab, through the valley of death, to the successful implementation with survival benefits.

Methods

With bibliometric data, we focused on and term co-occurrence network to see the map and the clusters of Her-2 research. We further do link analysis on the network. With all these methods, we will map the translational process of Her-2 research.

Mapping and clustering in a term co-occurrence network

We conducted mapping and clustering of terms in co-occurrence network of Her2-research. Terms in each article represented the concepts the article described. Two terms were considered as linked if they both occurred on the same article. The terms and their co-occurrence links constituted a term co-occurrence network, used to provide a graphic visualization of potential relationships between concepts represented within the collection of articles on a specific topic. Mapping and clustering techniques are frequently used to study such networks. Mapping is the creation of maps. We created a graphic, symbolic representation of significant features, using the distance between two items to reflect the strength of their relation. A smaller distance indicated a stronger relation. Clustering assigned a set of elements into clusters of similar elements, with a high density of within-group links and a lower density of between-group links. The stronger the link strength between two terms, the more likely was the categorization into the same cluster. Mapping and clustering techniques were based on similar principles to enhance the analysis transparency and to avoid unnecessary technical complexity and inconsistencies between the results produced.

Link analysis

We used link analysis - a data-analysis technique used to evaluate relationships between terms and clusters. How links occur within and between clusters and which terms are connected by these links, are the key factors to understand the relationship of the clusters and properties of a cluster.

Result

Mapping and Clustering Slamon's publications

Dennis Slamon and his team found a correlation between relapse and survival with amplification of the Her-2 oncogene, which became a significant prognostic factor. Since Her-2 is an oncogene that controls the growth of cancer cells themselves, Slamon tried to find a protein, which binds to the Her-2 and prevents from relaying a signal for cancer cells stimulation.

The Web of Science contains 410 publications authored or co-authored by Slamon. We use VOSviewer to map and cluster Slamon's publications (Figure 1).

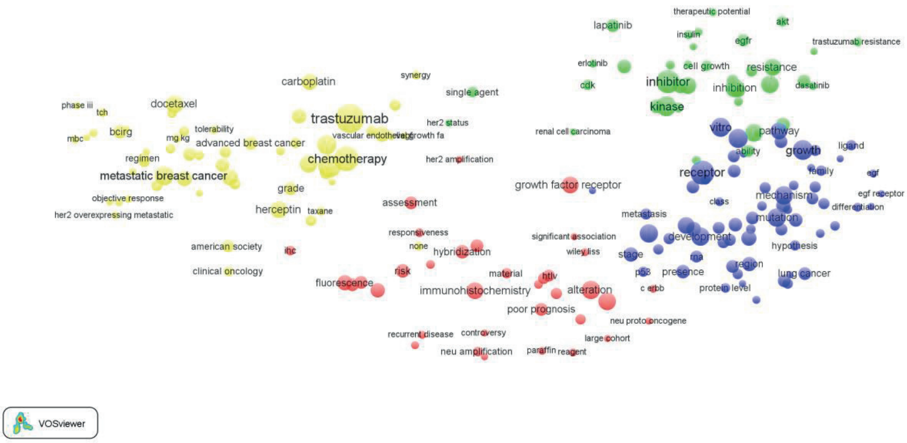

Fig 1. The clusters of Slamon's publications drawn by VOSviewer

The dots in the map represent terms drawn from the Slamon's publications. Different colours represents different clusters. So the landscape drawn by Slamon's publications has four clusters: The clusters of the green and the blue are on the right side of the landscapes, whose topics refer to the basic biological properties of the Her-2 oncogene, thus to fundamental research; The cluster of the yellow and red are on the left side, whose topics concern clinical practice. We name the clusters according to the terms in each clusters as showed in table 1.

Table 1. The summary of the four clusters's characteristics.

Colors	*clusters' name*	*Subclusters' name*
Green	Biological inhibiting mechanism	Her-2’ s biological property Development of cancer
Blue	Biological correlation mechanism	
Yellow	Clinical & pharmacology	
Red	Detection & diagnosis	

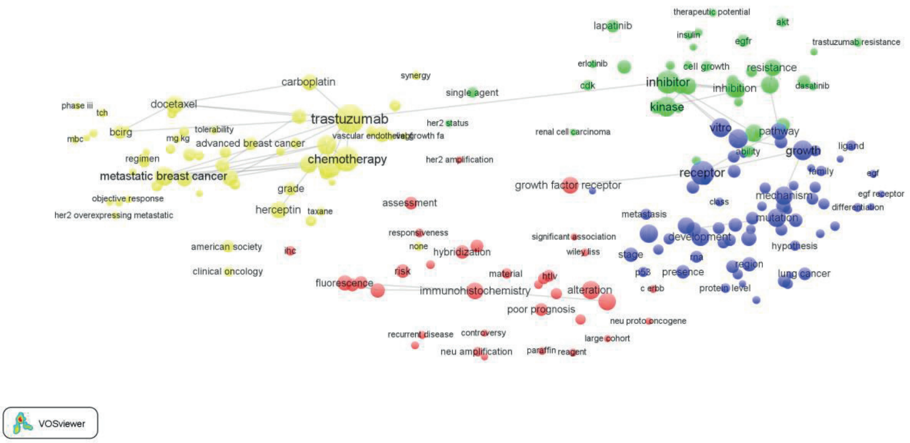
In the knowledge landscape drawn by Slamon's publications, the blue cluster emphasizes the biological mechanism of revealing the relation between biological properties of the Her-2 oncogene and the development of breast cancer. Hence the cluster has two parts: the basic biological property of oncogenes Her-2, which is at large near the green cluster; and the relation of these biological properties with the development of cancer, which is at large near the red cluster. However, the two parts are not completely separated. The biological mechanism constitutes the foundation of monoclonal antibodies therapy, in which Slamon mainly engaged. So we name this cluster biological correlation mechanism.

The links analysis for the landscape drawn by Slamon's publications

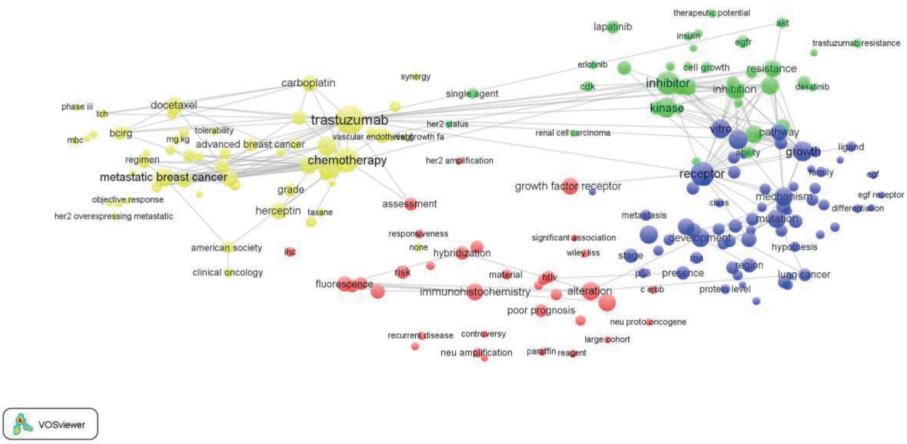
Link strength is the key factor to understand the formation of clusters in a map and the relation between clusters. We ranked the links by their linkage strength from strongest to weakest and studied them continuously increasing the groups (going further in the ranks).

A translation process does not occur till the discovery of a relation is found to be reliable. The reliable results can be verified and repeated. Repetition will make the linkage strength stronger and stronger.

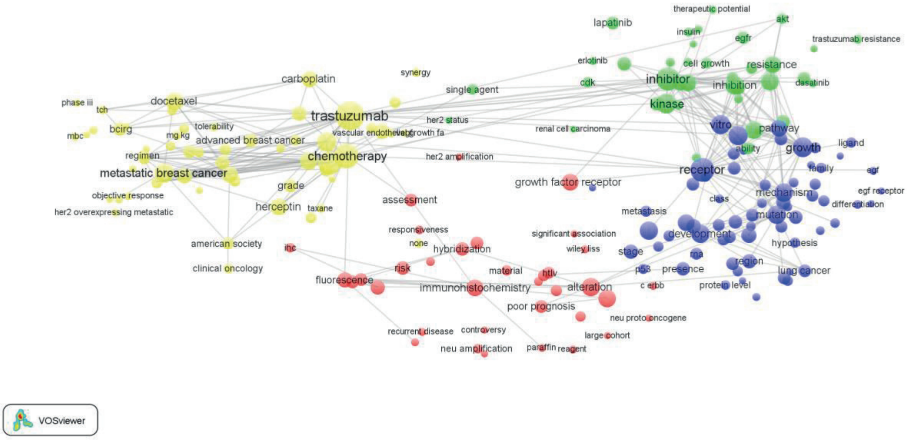
Figure 2 shows how the first 50, 200, 300 strongest links appear in the network.



(a)



(b)



(c)

Figure 2. Slamon's publication keyword co-occurrence network showing the 50(a), 200(b), 300(c) strongest links

The links within clusters

We noticed that indeed the strong links are more likely to occur within clusters: In Figure 2a, 23 out of the 50 strongest links occur within the clinical and pharmacology cluster (yellow). The words linked together by the strongest links were *trastuzumab, chemotherapy, carboplatin, cyclophosphamide, docetaxel, bcirg, dose, safety, efficacy* and *metastatic breast cancer (MBC)*, indicating that Slamon performed many trials to study the efficacy of the therapeutic regimes of trastuzumab with different chemotherapy antitumor agents.

Within the biological inhibiting mechanism cluster (green), two centers are formed by the first 50 strongest links. One is the term *inhibitor (inhibition)*, and the other *activation*. Inhibitor links to words such as *proliferation, apoptosis, panel, kinase* (which is an enzyme that catalyzes the transfer of phosphate groups from high-energy, phosphate-donating molecules to specific substrates, based on which the Her-2 proliferation can be inhibited). The term *activation* links to *resistance* and *kinase*. It further links to the word *pathway* in the blue cluster. *Inhibition* and *activation* describe reverse processes. Interestingly, though the two centers do not link directly (two centers are linked via the word *kinase*), each of them links to a word that is opposite to itself, hence to words that are similar to the other. This indicates Slamon's effort to find the apoptosis mechanism of Her-2's proliferation by activating or resisting some biological substances via kinase.

Only a few of these 50 strongest links appear in the biological correlation mechanism cluster (blue). Two parts of this cluster do not link together by the strongest links: in the part of basic biological property of oncogenes Her-2, the term *growth* are linked with the terms of *receptor*, *model* and *mechanism*. There are three links between the terms *receptor* and *pathway*, the terms *model* and *vitro*, the terms *loss* and *mutation* respectively in this part. In the part of the relation of these biological properties with the development of cancer, only one link connect the terms, *nsclc* and *non small cell lung cancer* (nsclc). These strongest links in this cluster do not make a lot of sense: *growth* and *receptor*, are the words in the phrase of *growth factor receptor*, *nsclc* is the acronym for *non small cell lung cancer*. Two parts in the biological correlation mechanism cluster (blue) remain separated even if the number of links increases to 100 (Figure 2b). However, we notice that from the link from the term *mutation* in the middle of the cluster stretches down to the term *loss*, which is tangled together with the part of the relation of these biological properties with the development of cancer. We know that loss or mutation of tumour suppressor gene is one of the reasons that lead to tumorigenesis. Two parts in the biological correlation mechanism were not connected when the number of links increase to 100. However, when it increase to 110, two important links from the term *mutation* to the phase *non small cell lung cancer*, and the term *mechanism* to the term *development* appear. As the number of links increase, five radiate centers, the terms of *receptor, growth, mechanism, mutation and development*, are formed.

In the detection and diagnosis cluster (red), only the terms describing the methods of detecting Her-2 status such as the *immunohistochemistry* and *FISH (fluorescence in situ hybridization)* are connected by some of the first 50 strongest links. The term *growth factor receptor* and *assessment* are in the middle of the map, but, the term *assessment* does not link to other words that describe Her-2 status' detection skills until in Figure 2(c), with the first 300 strongest links, the links from *assessment* to *immunohistochemistry* and from *immunohistochemistry* to *paraffin* appear within this cluster. G*rowth factor receptor* has no connection with the other terms in this cluster till the number of links increases to 600 via a link to *immunohistochemistry*. Weaker links provide cohesion to this cluster.

The links between clusters

Only six out of the fifty strongest links appeared between clusters (Figure 2a). Five of them stretch out from the blue cluster. Four of them appear between the biological inhibiting mechanism (green) and the biological correlation mechanism cluster (blue). These two clusters have higher link strength than others. This also explains why these two clusters are mapped closer to each other. Another one of the strongest links between clusters appears in the biological correlation mechanism cluster (blue) and the detection and diagnosis cluster (red) via a line between *receptor* and *growth factor receptor*. This link represent the bridge between the part of Her-2's biological property and biological inhibiting mechanism. Another important link between these two clusters is that from the term *development* to the term *alteration*, which appears when the number of links increase to 150, representing the bridge between the part of development of cancer and the biological inhibiting mechanism.

One of the six strongest links between clusters appears in the biological inhibiting mechanism cluster (green) and the clinical and pharmacology cluster (yellow) via a link between *trastuzumab* and *inhibitor*, which points to therapeutic principle used in clinical practice: trastuzumab is used as an inhibitor of the growth of the Her-2 oncogene.

These six links connect four clusters. The clinical and pharmacology cluster (yellow) is not connected to the detection and diagnosis cluster (red) (Figure 2a) despite their proximity on the map. The clinical & pharmacology cluster (yellow) links to the detection and diagnosis cluster (red) via links from *chemotherapy* and *trastuzumab* to assessment, when the number of strongest links increases to 200 (Figure 2b). In Figure 2c with the first 300 strongest links, an important link, from *trastuzumab* to *fluorescence*, is added between the clinical and pharmacology cluster (yellow) and the detection and diagnosis cluster (red). This link goes further to *neu gene amplification* in the detection and diagnosis cluster. The new links imply two methods to detect the status of Her-2: one being immunohistochemistry, which is based on the protein expression of Her-2 oncogene, and one being the gold standard, FISH (Fluorescence in Situ Hybridization), based on the Her-2 gene. This suggest that the detection of Her-2 status is crucial to decide on whether the drug trastuzumab should be applied or not.

The clusters at the end of diagonal lines, the clinical and pharmacology cluster (yellow) versus the biological correlation mechanism cluster (blue) and the biological inhibiting mechanism cluster (green) versus the detection and diagnosis cluster (red), are not linked to each other by the first 50 strongest links in Figure 2a. The clinical and pharmacology cluster (yellow), is linked to the biological correlation mechanism cluster (blue), via the term *trastuzumab* to the term *vitro* (when the number of links is smaller than 100), *model* and *receptor* (when the number of links is larger than 150 but smaller than 200). The red cluster, via the term *growth factor receptor*, is connected to the term *inhibitor* in the biological inhibiting mechanism cluster (green) by one of the 250 strongest links.

Discussion

In order to analyze how one TR stage is translated to another during bringing findings of fundamental research into medical and nursing practice, or, vice versa, we need to know how to mark different phases of the translational process and how to chart the pathways along these phases.

Clusters and the phases of Translation research

Her2 gene and its implication in the breast cancer treatment is one of the most representative examples of a knowledge transfer from the bench to the clinic and back. Since the Her-2 oncogene was identified, scientists have begun to study its biological properties. Using the knowledge of medicine-based molecular biology, they tried to discover the biological mechanism of linking the Her-2 protein with cell-growth of breast tissue. The mechanism is called biological inhibiting mechanism. Through this mechanism, scientist find the her-2 gene can stimulate human's own immune system to attack cancer cells or by giving immune system components, such as man-made immune system proteins (American Cancer Society, 2016) to cure the cancer. Since then, scientist began to study Her-2's biological process for immunotherapy. Based on these two mechanisms, Herceptin was created to break this link. When this succeeded in animal experiments and clinical trials, the drug was approved by the FDA and entered into the clinical practice. Hence, her-2 research come to a stage of clinical & pharmacology. For deciding on whether the drug can be used in patients depends on patients' Her-2 status, different methods were invented to detect Her-2 status. Based on detection, different therapeutic regimes were used to treat breast cancer in clinic. Detection and diagnosis are link together in the clinic practice.

However, the blue cluster in Slamon's landscape emphasizes the biological mechanism of revealing the relation between biological properties of the Her-2 oncogene and the development of breast cancer. The biological mechanism constitutes the foundation of monoclonal antibodies therapy, in which Slamon mainly engaged. The drug invented by Slamon, namely trastuzumab, is a monoclonal antibody against the Her-2 protein. It attaches to and blocks antigens on cancer cells so that they stop growing.

Slamon was the first scientist to find a correlation between the Her-2 oncogene and development of breast cancer. He made a thorough investigation of the biological mechanism of revealing the relation between biological properties of the Her-2 oncogene and the development of breast cancer.

So, we may say that the clusters of Her-2 publications exactly represent the phases through which the research topic went. The methodology of clusters and links between them allows identifying the relations between the topics. The maps then visualize the pathways connecting the clusters.

links and the bridge between the valley of death in the process of translation

As expected, the strongest links occured within the clusters. 23 out of the 50 strongest links were found within the clinical and pharmacology cluster (yellow). The other 27 were in the other three clusters. Term *inhibitor (inhibition)* and the term *activation* are the opposite centers formed by the first 50 strongest links within the biological inhibiting mechanism cluster (green). Only a few of these fifty strongest links appear in the biological correlation mechanism cluster (blue). Two parts of this cluster did not bind together till the strongest links increased to 200. In the detection and diagnosis cluster (red), only the terms describing the methods of detecting Her-2 status such as the *immunohistochemistry* and *FISH (fluorescence in situ hybridization)* were connected by some of the first 50 strongest links. The term growth factor receptor and assessment are in the middle of the map. The term *assessment* did not link to the other words that describe Her-2 status' detection skills until the number of strongest links increase to 300. *Growth factor receptor* had no connection to other terms in this cluster till the number of links increases to 600 via a link to immunohistochemistry.

Only 6 out of the 50 strongest links connect the clusters. Four of them appear between the biological inhibiting mechanism (green) and the biological correlation mechanism cluster (blue). Most of the links ranked by strength ranked between the 51st -100th strongest appear within or between these two clusters, which are also mapped closely. All these findings indicate these two clusters are closely related.

One of the six strongest links were between clusters appears in the biological inhibiting mechanism cluster (green) and the clinical and pharmacology cluster (yellow) via a link between *trastuzumab* and *inhibitor.* Another one of the strongest links between clusters appears in the biological correlation mechanism cluster (blue) and the detection and diagnosis cluster (red) via a line between *receptor* and *growth factor receptor*. This underlines the translational process that lead to the development of this medicine from the basic science profile.

We have also detected weaknesses of the TR processes, such as in the link between the clinical/pharmacology cluster (yellow) and the detection/diagnosis cluster (red). They are connected via links of *chemotherapy*, *trastuzumab* and *assessment* only when we increase the number of strongest links to 200. With the first 300 strongest links, an important link, from *trastuzumab* to *fluorescence*, is added between the clusters, which goes further to *neu gene amplification* in the red cluster. In general, the links between the cluster of the Her-2 status detection (red) and other clusters are the weakest. This proves that the importance of Her-2-detection came up only later in the TR process. The biological inhibiting mechanism cluster mainly deals with how over-expressed Her-2 in genes can be inhibited; the biological correlation mechanism cluster reveals the relation between Her-2 oncogene and the development of breast cancer. Correlation between the Her-2 oncogene and development of cancer inspired scientists to find ways to inhibit Her-2 oncogene as a therapeutic principle. The weakness of the links imply two methods to detect the status of Her-2: one being immunohistochemistry, which is based on the protein expression of Her-2 oncogene, and one being the gold standard, FISH (Fluorescence In Situ Hybridization), based on the Her-2 gene. This suggests that the detection of Her-2 status is crucial to decide on whether the drug trastuzumab should be applied or not. The separation of the links reflects the fact that Her-2 status test was not strictly conducted in the clinical practice at the beginning. The gold standard for Her-2 status detection – FISH - was approved by the FDA in 2002, four years after the drug has been used in clinical practice. In 2007, the Her-2 status test in breast cancer was recommended by ASCO-CAP. In 2013, ASCO-CAP convened an Update Committee that included co-authors of the 2007 guideline to conduct a systematic literature review and update recommendations for optimal HER-2 testing(Wolff, et al.2007,2013). The links between the cluster of the Her-2 status detection (red) and other clusters are also weak. This also indicates that Her-2 status detection was not considered to be important in the beginning. However, nowadays it has become a standard in breast cancer diagnostic and therapy choice.

The clinical and pharmacology cluster (yellow), the biological correlation mechanism cluster (blue), the biological inhibiting mechanism cluster (green) and the detection/diagnosis cluster (red) are not linked to each other by the first 50 strongest links.

The weaker links between the cluster of the Her-2 status detection and diagnosis and between two parts within the clusters of biological correlation mechanism are very important to understand the translation process of Her-2 research. The relations not only influence the usage of the drug trastuzumab, but also indicate the trends of therapeutic development: Herceptin was approved by the FDA only in 1998 for treating metastatic breast cancer; since then, a series of clinical trials evaluating the potential use of Herceptin for the adjuvant treatment of early-stage HER2-positive breast cancer in patients with early-stage HER2-positive, node-positive breast cancer; in 2008, Herceptin was approved as a single agent for the adjuvant approach. Finally in 2010, it was approved to treat patients with HER2-overexpression in metastatic gastric or gastroesophageal junction adenocarcinoma.

Conclusion

Her-2 research is typical translational research. This has an uttermost importance since Her2 research is finding its way to various clinical practices and policies. We have established the research clusters, linkage strengths between them and discovered weaknesses of some connections, which reflect the chronological transition of scientific processes and policies. Further investigation of the relation between the linkage strength and translation process is warranted. Our work is the first to target Her2 research in terms of systemic analysis, research design and concepts. For the first time, as to our knowledge, we establish structured models and processes describing Her 2 translational research, describing the results on the background of the translation into practice. It is important for both practitioners and researchers to have a control tool and be able to follow the translation of evidence-based Her2 guidelines into routine clinical-, community-, and policy-based practice.

Abstract

This paper proposes a method of reducing the noise of scientific citations in patents in order to show the real reference relationships and thus ensure the accuracy of the results of the follow-up study. First of all, based on the analysis of the sources of patent citations, and citation purposes as well as roles, this paper establishes that some of the scientific citations have lower similarity with patent documents. This we name citation noise. Then drawing upon the vector space model, this study builds a noise reduction model of scientific patent citations, and calculates the degree of similarity between the patents and their citations in order to filter the citations with low similarity. In the process of text similarity calculations, we consider semantics based on latent semantic indexing to increase the accuracy. The results contribute to accurate analysis of the knowledge flow between scientific research and technical innovation and provide data support for further research.

Introduction

Scientific knowledge is the driving force behind technological development and economic growth (He and Deng, 2007; Klitkou and Gulbrandsen, 2010; Callaert and Grouwels et al., 2011). Understanding the nature of the relationship between scientific research and technological innovation contributes to the guidance of science policy making, the improvement of technological performance and the realization of national prosperity (Guan and He, 2007). Consequently, substantial research has been undertaken to investigate the interaction between science and technology (Li and Chambers et al., 2014; Sung and Wang et al., 2015; Chen, 2017).

In the process of exploring the technological value of scientific research, the common quantitative methods include citation analysis (Hegde and Sampat, 2009; Li and Chambers et al., 2014; Chen, 2017), author-inventor name matches (Breschi and Catalini, 2010; Wang and Guan, 2011), performance of academic inventors (Meyer, 2006; Lissoni, 2010) and author-inventor co-publications (Klitkou and Gulbrandsen, 2010). Among the various citation analysis techniques, science linkage, which refers to the average number of scientific non-patent references (SNPRs) of patent documents, provides a useful perspective and consequently has gained popularity in scientometric literature (Narin and Hamilton et al., 1995; Narin and Hamilton et al., 1997; Huang and Yang et al., 2015; Sung and Wang et al., 2015; Fukuzawa and Ida, 2016). The SNPRs represent the knowledge flows from science to technology or more specifically, indicate the contribution of scientific knowledge to technology advances (Shearer and Lundeberg et al., 1997; Van Looy and Magerman et al., 2007; Criscuolo and Verspagen, 2008; Sung and Wang et al., 2015; Chen, 2017; Ding and Hung et al., 2017). Given the extensive and consistent availability of patent databases, science linkage provides a systematic view and empirical evidence to illustrate the interactions between science and technology (Callaert and Grouwels et al., 2011; Li and Chambers et al., 2014).

Although SNPRs data serve as an effective instrument in studying knowledge flow between science and technology (Hu and Chen et al., 2007; Lo, 2010; Magerman and van Looy et al., 2010; Ding and Hung et al., 2017), there is a problem that should not be ignored: the SNPRs data contain noise and little has been done to filter it (He and Deng, 2007; Li and Chambers et al., 2014). According to US patent laws, the applicant should include the prior art when filing a patent application (Hicks and Breitzman et al., 2000; Tijssen, 2001; Criscuoloa and Verspagen, 2008). However, prior art cited in the patent application document might cause its disapproval if it overthrew the novelty of the application (Jaffe and Trajtenberg et al., 1993). In consideration of the legal consequences, inventors might omit relevant information strategically to gain an economic interest (Alcácer and Gittelman et al., 2009; Lampe, 2012; Li and Chambers et al., 2014), thus some of the prior art cannot indicate science linkage objectively. Accordingly, some scholars suggested that a future study should take into account the intrinsic limitation of the patent citations and further develop interpretation of the data (e.g., He and Deng, 2007; Jaffe et al., 2000).

US patent law requires both the applicant and the patent examiner to provide the related prior art during the patent application and examination period (Chen, 2017). These references serve different purposes, respectively. The applicant references are for the purpose of demonstrating prior art for the invention generally, while examiner references are for restricting the patent claims (Azagra-Caro and Mattsson et al., 2011). Based on the analysis of the citation motivations of quoters, Li et al. (2014) contend that the noise of SNPRs concentrates on the non-self-citation by inventor/applicant, and thus this part of references cannot indicate science linkage objectively. In contrast, the self-citation by inventor/applicant and examiner citations can disclose prior art and describe technological background more accurately and comprehensively, and consequently are effective to measure science linkage (Li and Chambers et al., 2014; Chen, 2017). These authors shed light on the noise of SNPR data, which is helpful for us better to understand the knowledge diffusion from science literature to patent technology. In fact, patent citation behavior is extremely complex and it is unbelievable that all non-self-citation by inventor/applicant are strategic citations and completely useless for us to study the science linkage (Alcácer and Gittelman et al., 2009; Azagra-Caro and Mattsson et al., 2011; Li and Chambers et al., 2014).

In the era of data explosion, the development of science and technology is becoming more data-driven and high-quality databases are particularly essential to achieve research breakthroughs (Yu and Ding et al., 2015). As the SNPR data accompanied by an amount of noise and overload of irrelevant information which will bring negative influences to the results, simply applying SNPR data to indicate knowledge diffusion is illogical and unreasonable (Li and Meng, 2010; Wang and Yu et al., 2012). Under these considerations, we employ the vector space model (VSM) (Salton and Wong et al., 1975), which is an important, mature and popular text similarity method of filtering the noise of SNPR, reducing the negative influences and achieving a better analysis of patent citations (Ahlgren and Colliander, 2009; Magerman and van Looy et al., 2010). Specifically, in order to increase the accuracy of text similarity calculations, we consider content analysis based on latent semantic indexing in the patent text mining process. Through integrating citation analysis with semantics analysis, this study will reduce the noise of scientific citations in patents effectively and reveal the real referential relationships.

The rest of this paper is structured as follows. The Section 'Literature review' discusses the topics related to the science linkage discussed in previous literature to develop a theoretical foundation for the follow-up study. The Section 'Data Collection' describes the details of the data gathering and preprocessing. The Section 'Research methods' introduces the vector space model. The Section 'Results and application' applies the model in a practical case study and discusses the results. Conclusion and future work directions are illustrated in the 'Conclusion and discussions' section.

Data collection

With reference to the prior studies (Li and Chambers et al., 2014; Huang and Yang et al., 2015; Sung and Wang et al., 2015; Chen, 2017; Ding and Hung et al., 2017), all the patents information used in this paper comes from the USPTO (http://patft.uspto.gov/netahtml/PTO/index.html), which provides reliable information on patent documents and is generally accepted by scholars. We adopted the following search terms which are used in previous researches (Zhang and Feng et al., 2017a; Zhang and Yu et al., 2017b). We constructed the origin database by retrieving and downloading the full text documents of patents. There are many types of documents referenced in patents, but not all of them are considered as scientific output (Ding and Hung et al., 2017). In order to process the follow-up study smoothly, following the approach of previous authors such as Lo (2010), Li and Meng (2010), Sung et al. (2015), and Ding et al (2017), we conducted a thorough selection process by removing the extra information, such as notice of allowance for U.S. application, international search report and written opinion, office action in corresponding application. As a result, only scientific papers were retained in the database.

Based on the patent citation information provided by USPTO (Alcácer and Gittelman, 2009; Yasukawa and Kano, 2015), we distinguished between the citations cited by application or examiner. Employing Web of Science and Google Scholar, we conducted a research of the details of scientific literature, such as authors, authors' organization, title, abstract and keywords. Drawing upon that information, we then further divided the citations cited by application into self-citation by inventor/applicant (literature written by inventors) and non-self-citation by inventor/applicant (literature written by other scholars). A total of patents in these two fields were identified, which are 423 and 376, respectively. The details of the data set are as shown as Table 1.

Table 1 Basic information of patent data in these fields

Research field	Number of patents	Number of citations by examiner	Number of self-citations by applicant	Number of non-self-citations by applicant
Pharmaceuticals	423	321	358	8235
Biosensor	376	144	208	4026

Research Methods

In the vector space model, the text information is transformed into the feature vector.

$$\mathrm{V}(\mathrm{d_j}) = (\mathrm{t_1}, \mathrm{w_{1j;}}\, \mathrm{t_2}, \mathrm{w_{2j;}}\ \ldots\ldots ; \mathrm{t_n}, \mathrm{w_{nj}}) \quad (1)$$

Where $t_i(i = 1, 2, \ldots\ldots, n)$ are the feature items corresponding to text d_j , and $w_{ij}(i = 1, 2, \ldots\ldots, n)$ are the weight of $t_i(i = 1, 2, \ldots\ldots, n)$ in d_j.

Matrix X is used to describe the relationship between text and feature items:

$$\mathrm{X} = \begin{bmatrix} \mathrm{w}_{11} & \mathrm{w}_{12} \cdots\cdots & \mathrm{w}_{1n} \\ \mathrm{w}_{21} & \mathrm{w}_{22} \cdots\cdots & \mathrm{w}_{2n} \\ \cdots\cdots & \cdots\cdots\cdots\cdots & \cdots\cdots \\ \mathrm{w}_{m1} & \mathrm{w}_{m2} \cdots\cdots & \mathrm{w}_{mn} \end{bmatrix} = (\mathrm{X}_1, \mathrm{X}_2, \ldots\ldots, \mathrm{X}_n) = \begin{bmatrix} \mathrm{Y}_1 \\ \mathrm{Y}_2 \\ \cdots\cdots \\ \mathrm{Y}_m \end{bmatrix} \tag{2}$$

Where both column vector X_j and row vector Y_i represent the corresponding weights of the feature items.

w_{ij} is used to define TF − IDF factor by the following formula:

$$\mathrm{w}_{ij} = \frac{\log\left(\frac{\mathrm{N}}{\mathrm{df}_{ij}}\right) * \log(\mathrm{tf}_{ij}+1.0)}{\sqrt{\sum_{j=1}^{n}[\log\left(\frac{\mathrm{N}}{\mathrm{df}_{ij}}\right) * \log(\mathrm{tf}_{ij}+1.0)]^2}} \tag{3}$$

Where N is the total number of texts; df_{ij} is the number of texts which has feature item t in N; tf_{ij} is the frequency of a certain feature item in text d_j. Since many words appear less frequently, some elements in the matrix are zero. In order to reduce the amount of computation and storage space, and improve the efficiency of the computation, this study uses Latent Semantic Indexing (LSI) to reduce the dimension of the matrix.

In this process, singular value decomposition (SVD) is used to decompose the term-document matrix *X* into three matrices: a term concept matrix *U*, a singular value matrix *C* and document-concept matrix *V*: $X=UCV^T$ (Kontostathis and Pottenger, 2006). The top *K* dimensions of matrix *X* and *V* serve as the best approximation to the original matrixes. Each document is represented by a vector that shows the least square distances to the top *K* dimensions. There are three major advantages of LSI: synonymy, polysemy, and term dependence. Synonymy means that the same concept can usually be described by different terms. In LSI, the concept in question and other documents related to it are all described by a weighted combination of indexing variables. Polysemy refers to words that have a different meaning in a diverse context. An SVD of the term similarity matrix is available to combine with cluster analysis in order accurately to determine the sense of a particular word. LSI factors are orthogonal by definition, and words are positioned in the reduced space in a way that represents the correlations of their use across documents, which determines the characters of term dependence.

There are many formulas for text similarity, which include the inner product, cosine, Pearson and Manhattan distance formula. This paper employs the cosine formula which is as follows:

$$\mathrm{SIM}(\mathrm{d_i}, \mathrm{d_j}) = \frac{\sum_{k=1}^{n} \mathrm{w}_{ik}\mathrm{w}_{jk}}{\sqrt{\sum_{k=1}^{n} \mathrm{w}_{ik}^2}\sqrt{\sum_{k=1}^{n} \mathrm{w}_{jk}^2}} \tag{4}$$

Where $0 \le \mathrm{SIM}(d_i, d_j) \le 1$.

Results and Analysis

In this part, we apply the text similarity computing models described above to filter the noise in the non-self-citations by application to the fields of pharmaceuticals and biosensors. After that, in order better to describe the actual citation relationship, we calculate the science linkage using the following formula:

$$\text{NumSL\_NF=NumCE+NumSCA+NumNSLA\_NF} \tag{5}$$

In Eq. (5), $\mathrm{Num}_{\mathrm{SL\_NF}}$ is the science linkage after noise filtering; $\mathrm{Num}_{\mathrm{CE}}$ is the number of citations by examiner; $\mathrm{Num}_{\mathrm{SCA}}$ is the number of self-citations by applicant; $\mathrm{Num}_{\mathrm{NSLA\_NF}}$ is the number of non-self-citations by applicant after noise filtering.

We then set several thresholds for comparison. For example, if the threshold is 0.5, we will remove the citations having similarities with the citing patent which are less than or equal to

0.5. Overall speaking, the test similarities between patents and their scientific literature citations are relatively low, so we choose 0 and 0.05 as the threshold values.

To observe the distribution of the cited times of journals more directly, we provide the cited details of journals in these two fields. For these two fields Pharmaceuticals, and Biosensors, the total number of cited journals is 1215, and 780, respectively. The number of journals cited more than 100 times is 8, and 4, respectively. The number of journals which are cited between 50 and 100 times is 13 and 10, respectively. The number of journals of which the number of citations is between 10 and 50 are 123, and 70, respectively. The number of journals cited less than 10 times is 1071, and 696, respectively.

In order to observe the effect of noise reduction more intuitively, we provide the details of the top 15 journals listed in the field of pharmaceuticals and biosensors with the cited quantity under three conditions: without threshold, with the threshold of 0 and of 0.05, respectively. The details are shown in Table 2~Table 4.

Table 2~table 4 show that when processing with different thresholds, the journals' sequence and cited quantity changes with the total number of journals. The maximum value of similarity in the fields of pharmaceuticals and biosensors is 0.57 and 0.61, respectively. This result means that the test similarities are generally relatively low. According to the results in table 2~table 4, for the inventors in the field of pharmaceuticals, attention should be focused on the following journals: Journal of Medicinal Chemistry, PNAS, Journal of Biological Chemistry, Nature, Journal of Organic Chemistry, Science, Tetrahedron Letters, Journal of the American Chemical Society, and Tetrahedron. For the inventors in the field of biosensors, attention should be focused on the following journals: Analytical Chemistry, Sensors and Actuators B: Chemical, Biosensors & Bioelectronics, Journal of the American Ceramic Society, PNAS, Nature, and Science. As the top journals in the world, Science and PNAS appear in both the lists, which means that these journals record a large number of outstanding achievements in basic research.

Discussion

Based on the patent data of four representative fields from the USPTO, this paper focuses on the method of reducing the noise in patents' scientific literature citations. In terms of theoretical contributions, firstly, drawing upon analysis of the sources of patent citations, the citations' purposes as well as their roles, we found the main source of citation noise, which laid the foundations of the preceding analysis. Secondly, according to the characteristics of patent citation noise, this paper proposed the text similarity computing method based on the vector space model and latent semantic indexing to filter the patents' citation data. The results help to reflect the real citation relationship, measure the knowledge diffusion from scientific literature to technical innovation, and ensure the accuracy of the follow-up study.

With respect to practical contributions, firstly, filtering the noise of patents' scientific literature citations contributes to evaluating accurately the contribution of scientific journals. Based on different thresholds, we observed the change of the cited scientific journals' sequence and quantity, which helps to choose the appropriate scientific journals during technical innovation. Secondly, drawing upon the concept of journal impact factor (JIF), a technological impact factor (TIF) is proposed as a new indicator to evaluate the importance of a specific journal from the aspect of scientific research's contribution to practical innovation, and thus describe knowledge flow between journal papers and patents (Huang and Huang et al., 2014). However, this indicator ignores the noise in patents' citations, and the method proposed in this paper is very useful for improving the indicator.

The data used in this paper comes from the United States Patent and Trademark Office (USPTO). Different patent offices have diverse patent review mechanisms. The follow-up research can collect the patent citation data from other patent databases, such as the European Patent Office (EPO) and the Japan Patent Office (JPO) and make a comparison. The results can be applied to strengthen the discussion of the noise in patents' citations and illustrate the relationship between scientific literature and technological innovation.

Abstract

This preliminary paper investigates the cost of parenting engagement on academic productivity and impact. Instead of investigating the relationship between gender and academia, this study focuses on time invested in parenting as the lead factor underpinning productivity differences for both men and women. Survey responses from 17,519 first and last authors publishing between 2007 and 2017 yielded four distinct parenting types: Lead parents; Satellite parents; Sole parents; and Dual parents. In addition a free text box in the survey allowed for the analysis of 5976 qualitative responses about participant's experiences balancing parenting with their partners, and academic careers. Results show a significant difference across all types of parenting relative to gender for the number of papers produced, as well as for the proportion of papers published in top journals. In addition, for men and women who take on dual parenting roles (a hypothetical 50/50 split), the productivity cost is higher for women. Conversely, there is a significant cost for men and women who take on the role of Lead parent. Further qualitative investigation highlights the incidence of an 'invisible burden'in self-identified dual parenting families, wherein there is a significant amount of unacknowledged labor that is undertaken by females. This invisible labor may contribute to the difference in productivity between men and women in dual-parenting relationships.

Introduction

The gender gap in academe has been the focus of several analyses, which span from describing the various forms taken by this gap (Larivière et al., 2013; Nittrouer et al., 2015) to the mechanism that drive it (Leslie et al, 2015; Moss-Racusin,et al., 2012). Among those, differences in academic rank, organisational approaches, and the extent of specialisation (Leahey, 2006), the main explanation remains an assumption that women are faced with the majority of childcare (Beddoes & Pawley, 2014). As a consequence this restricts their ability to engage fully in the demands of the academy, directly influencing their academic productivity both in the short and long term.

No one denies that raising children demands a considerable amount of time and effort that diminishes the time and energy that can be devoted to scholarship and on academic earnings.

Barriers for women when pursuing academic careers in science include systematic barriers such as child rearing and the inability of research systems to allow the flexibility necessary to juggle research with home-responsibilities (Feeney et al, 2014; van Anders, 2004). However, this centralisation of women as the primary caregiver, and hence the majority of the time burden in previous research further blurs an understanding of the productivity cost of parenting. This is especially when variables other than childcare perpetuate the gender gap in academia.

The concept of "balanced" parenting is also a relatively new social change (Bright Horizons, 2017) that questions the relevance of past studies of how commitments to the academy and parenting are fulfilled. A more modern perspective on parenting also acknowledges that both parents, irrespective of gender or marital status, involved in a degree of parenting. In addition it also recognises parenting strategies that incorporate non-parental figures (e.g. grandparents/extended family; formal childcare provision etc) that take an active role in maintaining the work-life balance in academia. These more modern parenting models allow families to strategise children, childcare and full time careers (for both parents potentially) around academic demands. What is missing in an understanding of how parenting influences academic labor is the productivity and performance costs of modern parenting strategies.

Using a world-wide survey of academic parents (n=17,519 respondents), this research in progress uses the term "parent" as gender neutral, acknowledging that modern parenting is a joint, or multiple-partner endeavour. As such, this research aims to avoid ascribing loss of productivity on a single individual "parent" alone, in order to further investigate the parenting cost on academic productivity.

Methods

Survey

Web of Science was used to sample all first and last authors who had published at least one article in the period 2007-2017. All authors were then invited to complete an online survey. The first survey question used skip logic to eliminate all potential respondents who were not parents. In total, 17,519 individuals who met this initial filtering requirement responded. Data cleaning was done to exclude unfinished responses and erroneous responses (e.g., doctoral degrees obtained before birth) and to account for missing data resulted in a final sample of 10,444.

Survey questions included: demographic information on children and partners; contribution to childcare; the balance of parental labor with other caregivers; and their perception of the relationship between childcare and academic careers. The underlying hypothesis guiding survey construction was that it was not the parental status, but rather time allocated to parenting that would lead to decreased productivity.

Quantitative Methods

The analytic set included the 10,444 respondents with complete surveys. ANOVA was used to test the null hypothesis that the mean productivity (i.e., number of papers) and impact (i.e., proportion of published papers that are considered highly cited relative to field and year (PPTop)), is the same for parenting type relative to gender (gender/parenting type categorisation). Permutation tests were used as a post hoc test comparison to further test the relationship between the gender/parenting type categorisation. Here, two test statistics were used; one that measures the square distance between each observation and the group mean; and the other measuring the difference between the group median.

Qualitative data

A free text section was included at the end of the survey that encouraged participants to *"Please feel free to add any additional comments you have regarding childcare and scientific labor, drawing upon your own experiences".* In total, 5976 participants completed this section. To analyse this, a random sample of 500 was selected and coded thematically using a grounded theory-informed approach. Themed categories were developed (n=59) and then collapsed into 8 overarching thematic codes capable of facilitating the manual coding of large numbers of responses.

Results

A breakdown of how respondents described their involvement in parenting is shown below in Table 1.

Table 1. Proportion of respondents (Male and Female) in different parenting styles

Parenting style	*Male*	*Female*
I am the primary caregiver to my child(ren)	4.2	31.8
My partner is the primary caregiver to my child(ren)	33.2	4.0
The majority of childcare is performed by non-parental caregiver(s)/other	5.8	12.5
I share equal parenting roles with my partner	55.1	46.6
I share equal parenting roles with non-parental caregiver(s)/other	1.7	5.1
TOTAL	100	100

Here, 31.8% of female respondents indicated that they were the 'primary caregiver' to their children, compared with 4.2% of male respondents. In contrast, 33.2% of men indicated that their 'partner is the primary caregiver' to their children. A relatively equal proportion of male (55.1%) and Female (46.6%) respondents indicated that they 'share equal roles with my partner'. These results hid whether respondents were able to share parenting duties as a married and/or partnered relationship, and those were not but still "shared" parenting. Therefore the results of Table 1 were cross-referenced with marital stat gender/parenting type categorisation us to create the following parenting classifications.

Table 2. Classification of parenting types and proportion of respondents in each category

Parenting type	*Definition*	*Male*	*Female*
Sole parent	Are *'primary caregiver'* to their children AND are single/widowed/divorced or separated	1.1	6.5
Lead parent	Are within married/partnered relationships AND *'the primary caregiver'*	2.9	24.1
Satellite parents	Any relationship arrangement AND have a *'partner who is a primary caregiver'; or 'the majority of childcare is performed by a non-parental caregiver(s)/other'*	38.8	17.4
Dual parents	Any relationship arrangement AND have *'share equal parenting roles with a partner'*; AND *'share equal parenting roles with non-parental caregivers(s)/other'*	57.2	51.9

Although both genders report engaging in dual-parenting arrangements and/or as a satellite parent; 24.1% of women are acting as the Lead-parent whereas less than 3% (2.9%) of men act the same.

Figure 1. Number of papers by parenting type and gender (outliers removed)

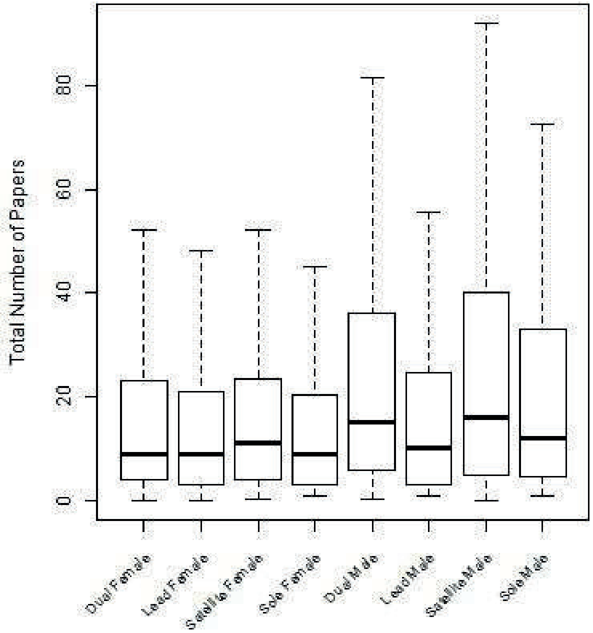

Figure 1 shows the average number of papers, with the outliers removed, for each parenting type relative to gender. A one-way ANOVA test was performed across all gender/parenting type categorisation showing a significant difference (F(leadparent) F=25.31 p<0.001), and a further two way test, showed interactional effects indicating that the effects of taking on the Lead parenting role on academic productivity are different for men and women F(gender:leadparent) F=3.34, p=0.01. Further, using a permutation test for the number of papers, the probability that the expected mean number of papers and median number of papers is not different for at least one gender/lead parenting level is almost 0.

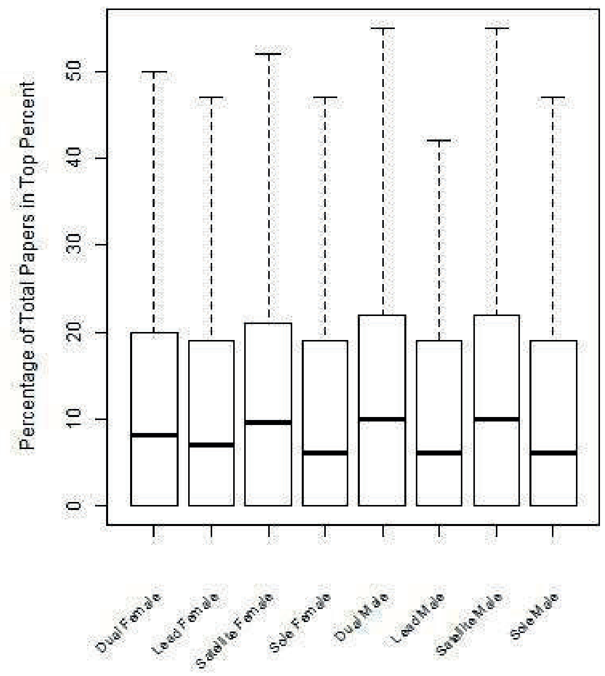
In addition, Figure 2 shows the proportion highly cited papers relative to field an year (PPTop) for each gender/parenting type categorisation. The single factor analysis shows how the expected percentage is different for at least on gender/parenting type categorisation (F=3.40, p=0.001). The two-factor interaction ANOVA indicates that while there is a difference in the expected percentage between males and females (F(gender:leadparent) F=0.15, p=0.92) , there is no difference for the lead parent role regardless of gender. Permutation tests verified this finding by showing a probability that the means and medians were the same for each gender/lead parent categorisation of close to 0 (=10^{-4}), p=0.0016.

Figure 2. Proportion of parent types by gender in PPTop



Qualitative results

A free text question allowed respondents to comment further on the survey or experiences balancing parenting with an academic career. In these responses, participants reflected on the flexibility of an academic career as being useful for allowing the time necessary to engage in parenting activities. However when the spouse was not an academic this flexibility was taken for granted as outwardly it seemed that they were *"not busy"*, resulting in parenting tasks being unconsciously conducted by the academic parent.

> *"It is hard to balance academic work and home life - as in many cases your partner does not understand that reading and working on your computer is your job. Thus, you find that you have various tasks (family, children, house, errands) thrown to you by your spouse who works a "regular" job because you are "not busy".*

The assumed-flexibility of an academic career also served to ingrain practices that burdened academic women with the majority of responsibility for parenting;

> *"I didn't want to miss out on anything and had the more flexible career, so I did most of the parenting roles. However, this eventually just became the habit of "how we did things" and my husband had time for hobbies while every moment of my time was taken up by work and kids."*

In addition, the invisible burden of parenting on academic women, and the flexibility of academic work that allowed parents to appear *"not busy"* by working at home, infiltrated the reasoning of dual-parents around who would assume the majority of the parenting responsbilities; “*Inevitably, we both feel that if a sacrifice must be made, it is my schedule”*. This decision was made irrespective of salary considerations.

In many cases, the adoption of invisible parenting labor was not a result of a conscious decision about how to divide roles between parents, but still incorporated a large temporal and emotional burden;

> *The mental labor of researching and remembering EVERYTHING related to kids activities and school falls to me - including selecting locations, remembering deadlines for sign-ups, getting proper equipment: summer camps, swimming lessons, dance, after school care, parties at school (bringing snacks/valentines etc.), field trips. It is constant, exhausting, and under-appreciated.*

Men who were part of dual-parenting arrangements acknowledged the existence of this invisible parenting labor burden on women; “*Although I try to be active in child care and share responsibilities equally, my wife still takes care of more child care tasks than I do”*. A further analysis of men in satellite-parenting arrangements also reinforced the benefits they accrue in academic productivity when their partner takes on the lead parenting role. Men in self-declared dual-parenting relationships also acknowledged the invisible burden on their partners; *I like to think we shared, but the wife apparently did more.*

Finally, there are benefits for women who adopt a lead-, and dual-parenting arrangement, provided that their partner takes a lead or dual-parenting role as well; “*The system was not perfectly equal in all regards, but he made every effort to make it as fair to both of us as possible. That is a big reason why I have had a successful career in science.*

Discussion

The results showed that there is a connection between the amount of parental responsibility assumed by an individual and research productivity as measure by the number of papers, and the proportion of papers considered highly cited for the field and year (PPTop). The model also show that there is a significant interaction with gender, suggesting that the link between parenting arrangements and productivity differs is different for men than it is for women. This study demonstrates how the level of parental responsibility is a powerful variable to explain academic productivity differences between men and women. Further research is currently underway to investigate these effects in more detail, which also includes a deeper understanding of the nature of the invisible parenting labor burden, and its interactions with the parenting typologies and academic productivity and impact.

Abstract

To satisfy the needs of the development of science and technology for diversified fronts exploration, this paper proposed a fine-grained way to identify different types of research fronts from the author-level aspect. We selected high yield authors and applied burst detection algorithm to detect burst terms from representative prolific authors, then extracted additional attributes from their papers. Based on the attributes, we created some indicators to define different types of research fronts. A case study in the field of Artificial Intelligence (AI) had been done and we got 13 emerging research fronts, 19 growing research fronts and 38 hot research fronts. Emerging research fronts depict specific research directions or definite applications, growing research fronts reflect the transition from the emerging research fronts to the hot research fronts, while hot research fronts mostly represent basic method or theories in the field. Our results show enlightenments to related researchers and give suggestions to policy makers, administrators or funders. Further works will focus on testing much more high yield authors to explore the impact on the results with regard to the number of authors.

Introduction

The study of research front has become a hot topic in recent years. From 2013 to 2017, Institutes of Science and Development, Chinese Academy of Sciences (CAS) and Clarivate Analytics joint released a series of reports of *Research Fronts* based on the Clarivate Analytics database Essential Science Indicators (ESI). These reports have gained widespread attention from around the world, the *Physics World* ever cited fronts in physics identified by *Research Fronts 2016* (Physics World, 2016).

Understanding the latest developments or tracking emerging specialty areas provides a distinct advantage for administrators, policy makers, and others who need to monitor, support, and advance the conduct of research in the face of finite resources. In the other hand, developments of science and technology have seen rapid increases in publications in years. In this condition, there is a commensurate increase in the need for scientific and technical intelligence to discover research fronts. However, new development in science and technology pushes new needs of diverse research fronts detection. Our study selects papers of high-yield authors as input to detect burst terms and classifies detected terms into different types of research fronts based on certain attributes, which puts emphases on identifying research fronts in a fine-grained way.

Related Works

The Definition of Research Fronts

The concept of research fronts was first introduced by Price (1965), he pointed out that there was a tendency for the most-cited papers to be also the most recent, and clusters of recent published papers with high citations indicated the nature of the scientific research front.

Persson (1994) believed that articles that were similar in terms of citing the same literature formed a research front. Morris, Yen and Wu et al. (2003) defined research fronts as clusters of documents that tend to cite a fixed, time invariant set of base documents. Besides these two views about the definition of research fronts, some researchers defined it from words or topics level. Braam, Moed and Van Raan (1991) regarded it as a coherent set of subject-related research problems and concepts upon which attention is focussed by a number of scientific researchers. More recently, Chen (2006) defined a research front as an emergent and transient grouping of concepts and underlying research issues. However, there is still no general consensus about the definition of research fronts. Considering that citation analysis methods are inadequate in depicting new emerging research fronts (namely the time lag), we identify research fronts from burst terms in this study.

Methods on Identifying Research Fronts

As Figure 1 shows, we classify existing approaches into qualitative methods and quantitative ones. Qualitative methods mainly include Delphi study, analysis of technology policy and comparative analysis etc. (Ran, Su & Zhao, 2017). They were widely used in the early stage of detecting research fronts, and were mostly applied to guide the work of making government technology strategies. However, those expert-based approaches, which utilize the explicit knowledge of domain experts, are often time-consuming and subjective in this information-excess era. Quantitative methods contain: (1) citation-based methods, including co-citation analysis (Small, 1973; Griffith, Small & Stonehill et al., 1974; Persson, 1994; Shibata, Kajikawa & Takeda et al., 2009), bibliometric coupling (Kessle, 1963; Persson, 1994; Huang & Chang, 2014), direct citation (Kajikawa, Fujimoto & Takeda et al., 2009; Shibata, Kajikawa & Takeda et al., 2009) and burst reference (Kleinberg, 2003; Fang, 2015; Hou, Yang & Chen, 2018); (2) word-based methods, including word frequency (Mane, 2004), burst term (Chen, 2006; Chen, Dubin & Kim, 2014; Song, Zhang & Dong, 2016) and co-occurrence (Callon, Michel & Turner et al., 1983; Rip & Courtial, 1984). However, as yet no consensus has emerged as to which of them has better detection performance (Huang & Chang, 2015). In our study, we use burst term detection and statistical attributes for identifying research fronts, which ensures both objectivity and timeliness of identified research fronts to a certain extent.

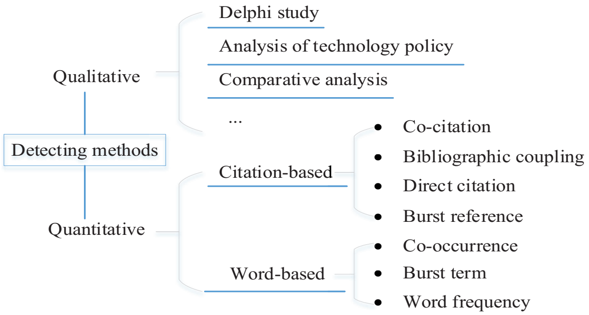

Figure 1. Taxonomy of methods on identifying research fronts

Types of research fronts

Looking back on existing researches, only a few researchers detected different types of research fronts. Upham and Small (2009) measured the growth rates of research fronts and categorized them as growing, shrinking, stable, emerging, or existing fronts. CAS and Clarivate Analytics (2017) joint released the *Research Fronts 2017*, and they selected hot research fronts and emerging research fronts from 9690 research fronts in 21 ESI fields. Total citations and the average year of fronts' core papers were regarded as two key factors in identifying hot research fronts, while research fronts whose core papers dated to the second half of 2015 or more recently (on average) and total citations were considered to define emerging research fronts. Based on previous work, we specify the definitions of several types of research fronts and make them more in line with the research needs in this era.

Data and Methodology

Research design

The research schema is depicted in Fig. 2:

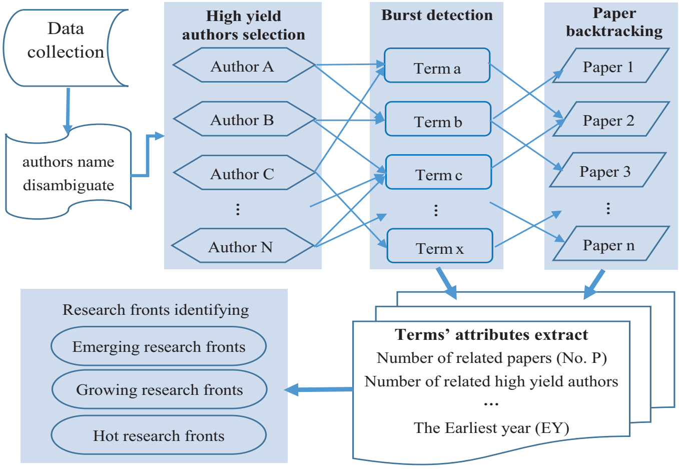

Figure 2. Research schema of this study

A main principle of identifying research fronts from a fine-grained way is that we do not use all publications in a field. Instead, we regard publications belonging to high yield authors as the research object. Follow the schema shows in Fig. 2, (1) we first combine authors' co-authors and institutes to disambiguate names, (2) then set the threshold and select prolific authors; (3) For each high yield author, burst algorithm was applied to the author's publications to detect burst terms; (4) for each burst term, backtrack related papers, match each burst term to related papers when the term appears in the title, the abstract, the keywords, or the keywords plus of a paper; (5) extract the publication year, the number of cited times and other attributes of a paper; (6) based on those attributes and further indicators, we define different types of research fronts and make detailed illustrations.

Note that burst term itself only provides limited information about the research front, so we focus on the author-level perspective and assign informative attributes to burst terms. We highlight it as an innovation of our study, since most previous studies using burst terms for detecting research fronts merely describe and explain burst terms but without combining other useful attributes. Table 1 shows descriptions of the attributes.

Table 1. Descriptions of terms' attributes

Attributes (Abbr.)	*Descriptions*
Number of related papers (No. P)	No. of related papers to a term
Number of related high yield authors (No. A)	No. of related high yield authors to a term

The earliest year (EY)	The earliest year that a term appeared (in our dataset)
The latest year (LY)	The latest year that a term appeared (in our dataset)
Average year (AY)	The average year of a term
Number of the earliest related high yield authors (No. EA)	No. of the earliest related high yield authors to a term
Number of the latest related high yield authors (No. LA)	No. of the latest related high yield authors to a term
Total citations of a term's related papers (TC)	No. of the total cited times of a term's related papers

After finishing those processes, we can form a matrix (Table 2), via which we define three types of research fronts in this study: (1) Hot research fronts, are identified by the PAC indicator we proposed in this paper:

$$PAC = \frac{No.P}{\max(No.P)} + \frac{No.A}{\max(No.A)} + \frac{TC}{\max(TC)} \qquad \text{(a)}$$

To detect hot research fronts, equation (a) not only considers the citations of a burst term, but also combines the number of related papers and related high yield authors. A larger PAC indicator always means a more likely the term be a hot research front. (2) Growing research fronts, are identified by the G indicator depicted as equation (b):

$$G = \frac{No.LA - No.EA}{LY - EY} \qquad \text{(b)}$$

The G indicator is the average number of increased researchers per year. The larger G value of a term, the higher growth rate a term has, and more likely be a growing research front. (3) Emerging research fronts, are only determined by time factor. We set a threshold of the earliest year of a term's appearance to define this type of research front. Above all, for each burst term, we have these three indicators to determine which kind of front it belongs to.

Data collection and processing

First, we used WosDownload.exe to collect bibliographic records from 1996 to 2017 with the search strategy as "WC = Computer Science, Artificial Intelligence", WoS core collection and BIOSIS Citation Index (BCI) were selected. All searches were done within May, 2018 and we got 726597 records. Second, after disambiguating authors' names, we got 1085 authors who published more than 50 papers (full-count) from 1996 to 2017 and defined them as high yield authors in this study. Considered that bibliographic records of every single author's publications would be an input for each author's burst detection, it would be a huge task if we did the same thing for all 1085 authors, so we took 70 representative authors from 14 countries (or regions) as our research sample. Those countries (or regions) were Top 14 with the greatest number of high yield authors and each country's Top 5 authors with the most publications were selected. Since research fronts depict new trends or new movements in a field, the burst detection selected those authors' papers published within the latest 10 years (2008-2017). To find the earliest year of a burst term, we match terms with papers of 1085 high yield authors with papers' publication year ranging from 1996 to 2017. Table 3 shows authors we selected.

Table 3. Selected high yield authors

Ranks	*Country /Region*	*No. of prolific authors*	*Top 5 authors (No. of publications)*
1	China	144	Jiao, Licheng(272)、Li, Xuelong(247)、Cao, Jinde(189)、Zhang, David(180)、Zhang, Lei(174)
2	America	75	Abraham, Ajith(235)、Shen, Dinggang(181)、Narayanan, Shrikanth S.(175)、Zhang, Huaguang(163)、Chellappa, Rama(155)

Results

Results of burst detection

For the 70 representative authors we got 212 burst terms after manually filtering terms having no specific meanings, such as *the-art method (the state-of-the-art method), novel method* and *good performance* etc. Limited by space, Table 4 only lists burst terms of 14 authors with the most publications in the corresponding country (or region), for full version please email to us.

Table 4. Excerpt from representative high yield authors' burst detection results

Authors	*Terms*
Tao, Dacheng	linear discriminant analysis; learning algorithm; dimensionality reduction; discriminative information; human visual system; local geometry; image classification; sparse representation; objective function
Jiao, Licheng	evolutionary algorithm; benchmark problems; spectral clustering; neural network; real-world data set; memetic algorithm;
Watada, Junzo	DNA computing; fuzzy random variable; neural network
Herrera, Francisco	fuzzy rule-based classification system; feature selection; membership function; nonparametric statistical tests; prototype selection; nearest neighbor classifier; noisy data; big data; fuzzy set; multi-class problems
Schuller, Bjoern	recurrent neural net; automatic speech recognition; long short-term memory; neural network; recurrent neural network
Yao, Xin	negative correlation learning; benchmark problems; many-objective optimization; evolutionary algorithm
Murino, Vittorio	generative model
Pedrycz, Witold	Neural network; genetic algorithm; feature selection; differential evolution; information granularity; main objective; optimal allocation; particle swarm optimization; justifiable granularity; time series
Yan, Shuicheng	learning algorithm; face recognition; visual classification; objective function; training data; learning framework; action recognition
Cho, Sung-Bae	activity recognition; mobile environment; bayesian network
Das, Swagatam	invasive weed optimization; multimodal optimization; search space; artificial bee colony; particle swarm optimization; differential evolution
Hong, Tzung-Pei	multiple minimum support; fuzzy data mining; mining algorithm; membership function; tree structure; real-world application; data mining; utility mining; high utility itemset; objective function; execution efficiency; pre-large concept; static database; original database; transaction deletion; synthetic dataset; search space; candidate generation; high-utility itemset
De Baets, Bernard	edge detection
Prade, Henri	fuzzy set; formal concept analysis

Finally, we collected those 70 authors' burst detection results as Table 5 shows. It includes Top 10 burst terms with the greatest number of related papers. Further calculations to define different types of research fronts are based on this table, and further discussion about this terms-attributes matrix will be introduced in the next part.

Table 5. Excerpt of the Terms-Attributes matrix

Three types of research fronts

The most cutting edges are (or partly are) emerging research fronts. We find 13 emerging research fronts in AI. From Table 6, we can conclude that most of emerging research fronts are specific research directions oriented or definite application situations oriented. For example, *bat algorithm* is used to solve the global optimal solution, *high-utility itemset* is a kind of research directions of pattern mining, and *multi-component robotics system* is a sub-research direction of robotic system. In general, these emerging research fronts are characterized by less attention (the number of the earliest authors is less than 5, and the number of the latest authors is less than 7) and low citations (only three of them have total citations more than 800).

Table 6. Emerging research fronts

Terms	*No. P*	*No. A*	*EY*	*LY*	*AY*	*No. EA*	*No. LA*	*TC*
High-utility itemset	33	7	2014	2017	2016	5	6	89
Bat algorithm	26	12	2014	2017	2016	3	6	55
Transaction deletion	12	8	2014	2017	2016	2	4	29
Target individuals	9	2	2014	2017	2015	1	1	36

Nonlocal self-similarity	23	21	2011	2017	2014	2	7	1267
Visual emotion challenge	20	11	2011	2016	2013	3	5	164
Deep learning	515	294	2010	2017	2016	1	106	3540
Malware detection	26	10	2010	2017	2015	1	4	143
Justifiable granularity	26	6	2010	2017	2014	3	1	218
Adversarial settings	8	3	2010	2016	2014	1	2	87
Multi-component Robotic system	7	1	2010	2015	2012	1	1	39

Before developing into hot research fronts, some emerging research fronts may turn into growing research fronts, whose growing rate (the G indicator) is no less than 3. G = 3 is a threshold could be acceptable in our test, which leads to a result of 19 growing research fronts. Table 7 depicts attributes of Top 10 research fronts with the most G value, and compared with emerging research fronts, growing research fronts gain much more attention from high yield authors.

Table 7. Excerpt from growing research fronts

Terms	*No. P*	*No. A*	*EY*	*LY*	*AY*	*No. EA*	*No. LA*	*TC*	*G*
Deep learning	515	294	2010	2017	2016	1	106	3540	15
Neural network	9299	877	1996	2017	2009	42	252	123547	10
Convolutional neural network	687	292	2001	2017	2016	1	109	4379	6.75
Optimization problem	2984	665	1996	2017	2011	2	125	62349	5.86
Learning algorithm	2939	752	1996	2017	2009	5	127	48517	5.81
Support vector machine	3353	697	1998	2017	2010	1	105	63102	5.47
Computer vision	2726	579	1996	2017	2011	8	110	59396	4.86
Big data	295	202	2004	2017	2015	1	62	1827	4.69
Face recognition	3005	467	1996	2017	2010	1	99	70280	4.67
Image classification	990	373	1997	2017	2012	1	91	17159	4.5

Note: the rest are: particle swarm optimization, genetic algorithm, sparse representation, evolutionary algorithm, feature selection, feature extraction, object function, dimensionality reduction and computational cost.

The threshold we select is PAC = 0.5, we define a term as hot research front when its PAC indicator is larger than 0.5, with which we get 38 hot research fronts in the end. In table 8, these research hotspots include some fundamental terms and method theories in AI, such as *neural network*, *learning algorithm*, *support vector machine*, *sparse representation* and so on.

Table 8. Excerpt from hot research fronts

Image segmentation	1730	497	1996	2017	2010	7	61	42367	1.1

Note: Table 8 lists Top 10 fronts with the most PAC indicator, for full version please email to us.

In general, these terms, which represent the essential theories and methods of the field of artificial intelligence, are the basis for any author to turn to this field for research. Therefore, from the perspective of a single author, these burst terms are the embodiment of his research interest or change of research direction, while from the perspective of the whole field, these research fronts represent the research hotspots in the field.

Conclusions

It is of highly valuable to research detections of fine-grained research fronts. In this paper, we identify several types of research fronts in a fine-grained way from the author-level aspect. Different from previous studies, we extract additional attributes of burst terms from their related papers, e.g., the number of related papers of a term, the number of related high yield authors, and the earliest year a term appeared. Based on these attributes, the earliest year of a term's appearance is used to define emerging research fronts, the G indicator for defining growing research fronts and the PAC indicator for hot research fronts. The results of our case study in AI have enlightenments to related researches: we get 13 emerging research fronts, illustrating specific research directions or definite applications; 19 growing research fronts, reflecting the transition from the emerging research fronts to the hot research fronts and attracting much attention at present and is likely to evolve into hot research fronts in the future; 38 hot research fronts, representing fundamental methods and theories in the field. The informative results could guide decision-makings for policy makers, administrators and other stakeholders. We only applied burst terms from the 70 representative high yield authors to explore research fronts, which brought the limitation that a larger dataset may lead to different results. Further works will put emphases on the result of more prolific authors, in the meanwhile, considering AI experts' advices in the process of defining research fronts from burst terms.

Acknowledgments

This study is supported by major bidding project of National Social Science Fund of China(16ZDA224) and Postgraduate Research & Practice Innovation Program of Jiangsu Province(SJCX18_0135).

Abstract

The question of the place of women in the various sciences is now widely discussed and studied. The field of economics and management is no exception and also requires a reflexive analysis of its practices. This study contributes to a better understanding of the place of women in these disciplines by characterizing the difference in levels of scientific collaboration between men and women (as measured by joint publications) in economics and management. First, the results show for the first time on an empirical basis that the practices of collaboration between men and women are quite different in management sciences compared to discipline of economics. Second, a regression analysis shows that there is a negative and statistically significant relationship between the Normalized Citation Score and the proportion of women per article in economics, which is not the case in management sciences. Results also show that international collaboration and the choice of journals significantly affect normalized citation scores.

Introduction

The question of the place of women in scientific research is widely discussed in all disciplines. The fields of economics and management are no exception and also require a reflexive analysis of its practices. Similarly, reflections on the productivity and "quality" of scientific research have become ubiquitous since the 1980s. Nowadays, no scholar can escape the evaluation of its activities (Pansu, 2013, Gingras, 2016). At the individual level, the "quality" of a scientific publication, an abstract property that some consider unmeasurable, can in fact be approached by measuring its "visibility", i.e. the number of citations it receives in publications by other members of the scientific community (Cronin, 1984). In the bibliometric literature, there are numerous analysis of scientific production both in terms of the choice of indicators and the analysis of the determinants of productivity and visibility of researchers, particularly the question of the difference between men and women (Cole and Zuckerman 1984, Xie et al., 1989, Leahey, 2006, Castilla and Bernard, 2010, Baccin et al., 2014, Mairesse and Pezonni, 2015, Nielsen, 2016, Nielsen, 2018). Despite the multiplicity of bibliometric studies devoted to the evaluation of research in economics and management, the analysis of the determinants of the visibility of articles has rarely been analyzed in these disciplines. Even less the study of the links between the impact factor of the journal, the social characteristics of the authors and the number of citations received.

Judge et al. (2007) analysis of the citation determinants of articles published in the top 21 management journals shows that the main factor in the visibility of an article is the journal in which it is published. Harzing (2016) shows that it is rather the topic studied by the article, as well as the profile of the author, that influences the visibility of publications in management. Starbuck (2005) and Singh et al. (2007) conclude that the evaluation of research articles based solely on the impact of journals provides erroneous results as to the "quality" of publications, given intra-review variability.

With regard to the link between scientific performances and gender, several recent studies have shown that gender gaps still persist in favor of men both in terms of productivity and scientific visibility (measured by the number of citations). Nielsen (2016) analyzes gender disparities in production, impact and scientific collaboration. It examines a sample of 3,293 Danish researchers (7,820 publications) of which 65% are men and 31% are women (4% indefinite). It shows the persistence of the gender gap in these indicators. Nielsen (2016) concludes that his findings raise deep concerns about the management of research organizations, characterized by an asymmetrical gender structure. This would call into question the validity of meritocratic explanations of discrepancies. For example, the age of the beginning of a scientific career directly affects the level of production of a researcher, as well as family commitments. According to Mairesse and Pezonni (2015), the gaps in production between men and women disappear if one control for differences in access to jobs and different working conditions between men and women.

Based on an econometric study, Nielsen (2017) analyzes the differences in academic impact in management sciences by gender. In a sample of nearly 27,000 publications and more than 6,500 authors, he concludes that women have a slightly greater impact than men, while remaining cautious about the representativeness of the sample and the possibility of generalization. Similarly, women have a larger share in the decile of the most cited publications in this area. However, in a more recent publication, Nielsen (2018) considers that the mere use of quantitative indicators can be very dangerous for the recruitment and promotion of researchers. Although these indicators may appear to be objective and reinforcing the "story of meritocracy", they are often biased ex-ante by the gender barriers. According to Nielsen (2018), these indicators must absolutely be accompanied by a qualitative assessment by peers.

Based on a large sample, the present study aims to (1) investigate the practices of collaboration between men and women in economics and management and (2) its effect on scientific visibility of the publications using an econometric model (Tobit regression). Our data, extracted from the Web of Science (WoS), cover global production as indexed in 300 journals in economics and 330 journals in management, with respectively 79,078 and 90,022 articles published between 2008 and 2015. A Tobit regression model was used to measure the relations between the different variables analyzed and the normalized score of citations.

Collaboration practices in economics and management

At the global level, scientific collaboration, measured by the number of authors per article, is relatively stronger in management than in economics. The proportion of articles co-published by at least two authors is 81% in management (almost half with at least 3 authors) against 66% in economics (see Figure 1). This is a global average and the results vary somewhat by country. This is a first interesting difference between these two disciplines.

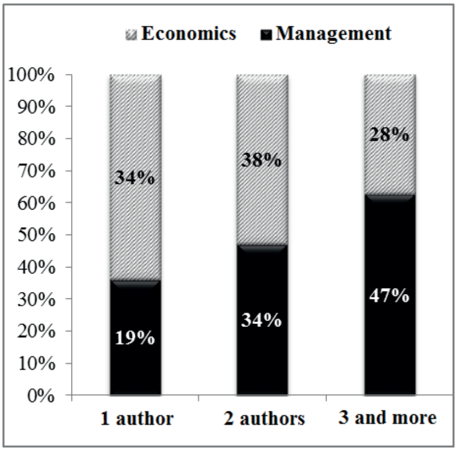

Figure 1: Number of authors per publication in economics and management

Figure 2 shows that the proportion of man-woman collaboration is much higher in management than in economics, 49% versus 27%. It also shows that the proportion of publication by women alone (without men collaboration) is three times higher in economics than in management (7% versus 21%). In economics, the majority of publications (52%) are signed by men and only 21% of women have published alone or with other women. In management, nearly half of the papers (49%) are the result of male-female collaborations. This is a second important observation on the disciplinary differences in male-female collaboration in these two disciplines.

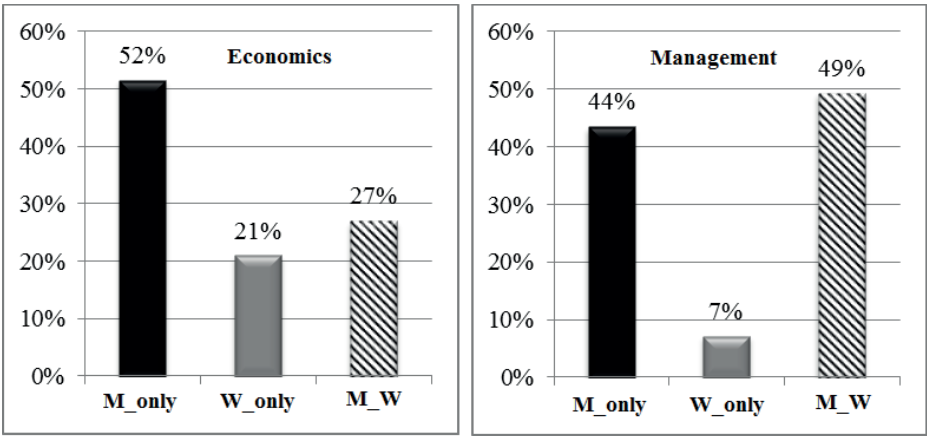

Figure 2: Collaboration between men and women in economics and management

Although the proportion of articles written in collaboration is greater in management, the distribution between national and international co-publications by gender is similar in both disciplines. This is true for co-publications that include only women, only men, or both (Figure 3). It should be noted, however, that women have a lower proportion of international publication than men.

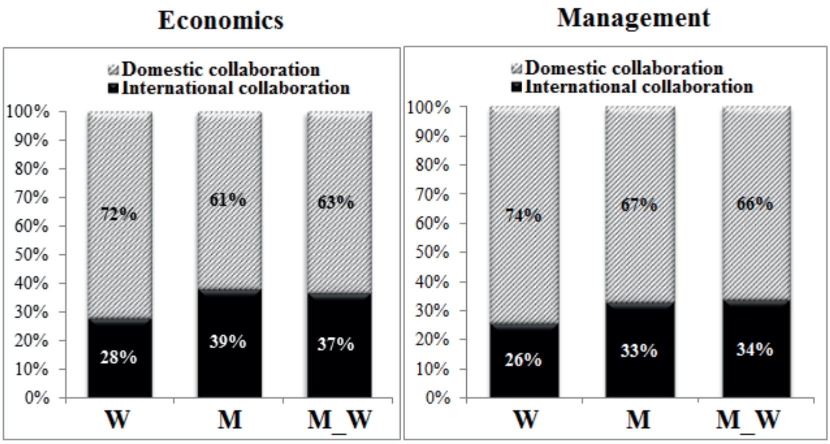

Figure 3: Proportion of articles co-authored according to the type of collaboration and gender

Figure 4 shows the gender distribution according to the CNRS classification of the journal in which articles are published. It can be seen that the proportion of articles published by women in the highest ranked CNRS journals (category 1) is slightly lower than that of men in the two disciplines, especially in management. Women in this discipline also publish more than men in journals classified in category 4, which are much less important in economics. We also observe that collaboration with men allows women to publish in higher-ranking journals.

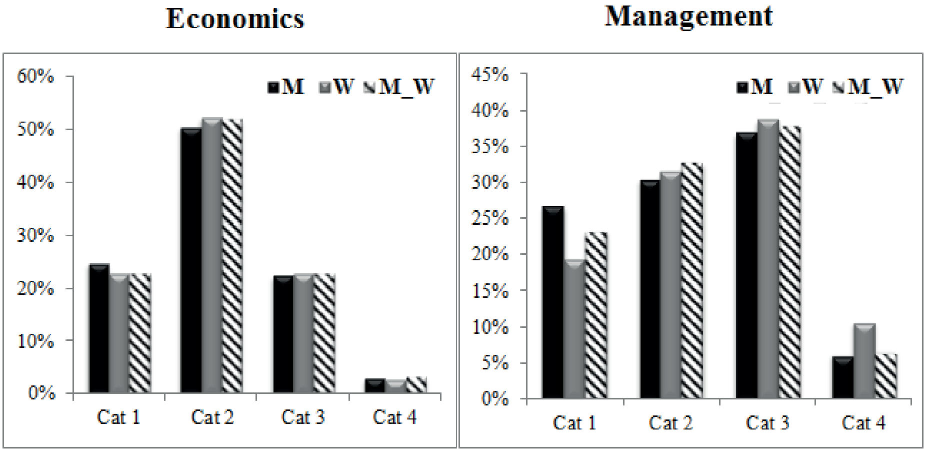

Figure 4: Proportion of articles by sex and CNRS categories of journals

Regression analysis

The database used for the regression analysis includes several information's about authors (names, gender and number), articles (publication year, title, Normalized Citation Score) and journals in which they are published (title, country of publisher, 2 years Journal Impact Factor and CNRS journal classification).

Dependent variable and model choice

The dependent variable is the logarithm of Normalized Citations Score (labelled Log (NCS)) received by each publication during the period 2008-2015. To retain the zeros, we have added 1 to the NCS before making the logarithmic transformation. Log (NCS) is a continuous variable with a lower boundary at zero and an upper boundary at infinity. Thus, a left censored Tobit regression model is used (see, McDonald and Moffitt, 1980) to account for the disproportionate number of observations with zero values, because a significant proportion of the observations in our sample are zeros. Tobit regressions avoid inconsistent estimates from Ordinary Least Square (OLS) regression.

Independent variable

In this study, we seek to analyze whether the gender of authors have an incidence on the number of citations received by scientific publications. To represent gender in scientific publications, we used the proxy of the proportion of women per publication labelled $Women\_Prop$. The authors' gender is assigned based on the methodology presented in Larivière et al. (2013), which uses the author's first name to assign a gender to them. For each of the articles in the two domains, we calculated the proportion of authors belonging to the feminine gender, using as denominator the sum of the authors to whom we assigned a gender. For example, an article with 5 authors, including two women, two men, and one unknown, was assigned a proportion of female authors of 0.5, leaving unknown cases out of the calculation. For an article co-signed by men only, the proportion is 0, and for an article whose all authors are women the proportion is 1. The values between 0 and 1 represent articles co-authored by both men and women. The higher the number of women per publication, the more the proportion is closer to 1.

For both disciplines, the proportion of women is lower than that of men. It is 32% in economics and 26% in management. These distributions are similar to the average of the global distribution of women researchers which is around 30% (UNESCO, 2018).

Control variables

A number of control variables are included in the model. The choice of control variables comes from the literature that shows that they are potentially associated with the number of citations received by publications. First, we control for the number of authors (Nbr_Authors) and the number of countries by publication, a proxy of international collaboration (Internat_collab). Second, we have controlled for the geographic origin of journals by building two dummy variables. The country of publisher was used as proxy of country of journals. US_Journal takes the value 1 if journal is American. $EU\_Journal$ takes the value 1 if journal is European. The non-American and non-European journals are the reference variables. Third, we control the impact of journals in which articles are published. In addition to the 2 years Impact Factor of the journal, we have constructed dichotomous variables to control for the journal classification of CNRS (2015). The CNRS classifies journals according to their degree of selectivity and importance in economics and management, thus providing a measure of their "quality". Four dummy variables were created. From $CNRS\_rank\_1$ that refers to the most selective journals in both disciplines, to $CNRS\_rank\_4$ that represent the least selective journals.

The regression model is written as follows:

$$\mathrm{Log}(NCS)_i = \beta_0 + \beta_1 Women\_Prop_i + \beta_2 Nbr\_Authors\ _i + \beta_3 Internat\_collab_i + \beta_4 US\_Journal_i + \beta_5 EU\_Journal_i + \beta_6 IF\_2_i + \beta_7 CNRS\_rank\_1_i + \beta_8 CNRS\_rank\_2_i + \beta_9 CNRS\_rank\_3_i + \beta_{10} CNRS\_rank\_4_i + \varepsilon_i$$

Using exactly the same variables, two distinct regressions were used for both disciplines. The aim is to analyze the differences between economics and management regarding the impact of gender on the citation score. The Table 1 resumes variables of model.

Table 1: Dependent, explicative and control variables of model

Dependent variable	
$\mathrm{Log}(NCS)_i$	Log transformed of NCS (Normalized Citations Score) by publication *i*
Explicative variable	
$Women\_Prop_i$	Proportion of women by publication. For example, for an article cosigned by 3 authors: 2 women and 1 man, the value will be 0.66 (66% of women). The value is between 0 and 1 (1 if all authors are women).
Control variables	
$Nbr\_Authors\ _i$	Number of authors by publication
$Internat\_collab_i$	International collaboration measured by the number of countries by publication
$US\_Journal_i$	It is dummy variable indicating the fact that the publisher of journal is American. It equal to 1 if it is.
$EU\_Journal_i$	It is dummy variable indicating the fact that the publisher of journal is European. It equal to 1 if it is.
IF_2	2 years Journal Impact Factor
$CNRS\_rank\_1_i$	It is a dummy variable representing categories 1, 1e, 1eg of the CNRS categorization of journals in Economics and Management. This category includes the most selective journals. It equal to 1 if it is, 0 otherwise
$CNRS\_rank\_2\ to\ 4$	Like $CNRS\_rank\_1$, variables $CNRS\_rank\_2\ to\ 4$ represents the journals of rank 2 to 4 of the CNRS classification. the degree of selectivity of journals decreases as the category increases

Before estimating the coefficients, we have verified the existence of multicollinearity. Multicollinearity is a problem that occurs when more than one of the model's predictor variables measures the same phenomenon. We are talking about multicollinearity when one of the explicative variables of model is a linear combination of one or more of the other variables introduced in the model. The absence of perfect multicollinearity is one of the conditions required to estimate a linear model. Two collinear variables are characterized in particular by a strong correlation. However, a strong correlation is not necessarily synonymous with collinearity. Both variables must, in addition, measure the same phenomenon. For example, the two variables $US\_Journal$ and $EU\_Journal$ are very negatively correlated (see Figure 5). This is normal since in our database a journal cannot be both American and European. On the contrary, the impact factor and the CNRS classification of journals measure more or less the same thing; the impact of journal. The difference between the two is that the impact factor is an objective measure based on the citations received by the journal, and that the CNRS classification incorporates a subjective dimension related to peer appreciation. The correlation test indicates that there is no strong correlation between the variables of model; all the correlation coefficients are less than 0.6 (see Figure 5: the larger and darker the bubble size, the higher the correlation).

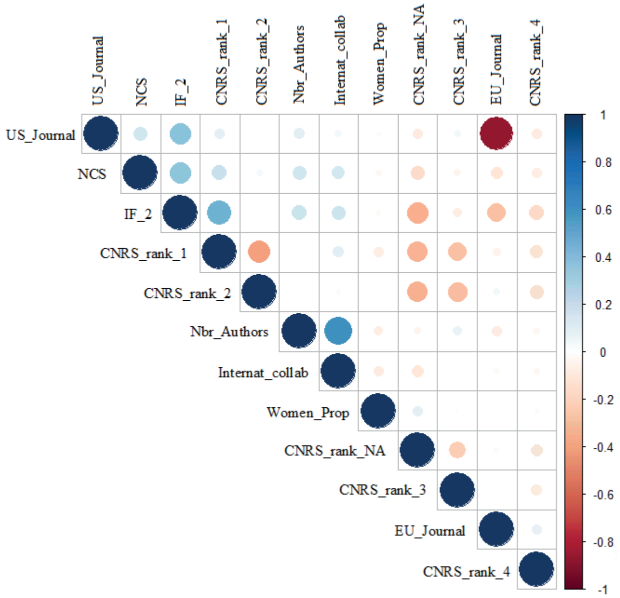

Figure 5: Correlation test of model variables

Results of regression analysis

In order to observe the interaction between the variables of the model, we chose to proceed by iteration. We can distinguish three types of explicative variables: sociological (proportion of women by publication, authors number and international collaboration), geographical (the fact that the journal is American or European) and bibliometric (impact of journals measured by Impact Factor and CNRS journal classification). This makes it possible to define three regression models; denoted respectively M1, M2 and M3. Tables 2 and 3 show, respectively, the regression results for economics and for management.

Table 2: Tobit maximum likelihood estimation, results for economics

Variables	(M1)		(M1) + (M2)		(M2) + (M3)

Tables 2 and 3 show four important results that we can summarize as follows:

The impact of gender on citation scores

In economics, there is a negative and statistically significant relationship between the Normalized Citation Score and the proportion of women per article. In other words, the number of citations decreases as the proportion of women increases. The value of the coefficient (-0.034) of the variable $Women\_Prop$ means that when the proportion of women increases by one unit (1%), the NCS decreases by 3.4%. Thus, for example, for an article with three authors, 2 men and 1 woman ($Women\_Prop$ = 0.33), if the number of women increases by one unit ($Women\_Prop$ = 0.50), the NCS decreases by 5.78% (17% * 3.4%). It should be noted that the value of the coefficient decreases as one includes in the regression new groups of variables. We also note that the coefficients are statistically significant in the three models.

For management, the finding is different. Table 3 shows that if we do not take into account the impact of journal (M1 and M2) there is a negative and significant relationship between the Normalized Citation Score and the proportion of women per article. As soon as the variables Impact Factor and CNRS journal classification are integrated (M3), the coefficient of the variable $Women\_Prop$ becomes statistically insignificant. Therefore, all things equal otherwise, there is no evidence of a significant relationship, either positive or negative, between the gender and citation impact in management. This result may be due to the very strong collaboration between men and women in management: more than half of the publications in this discipline are the corollary of the collaboration between men and women (see Figure 2).

The importance of collaboration

Regression results show that, for both economics and management, citations are positively and significantly shaped by: the number of authors and the number countries involved in a publication. This result is true for the three models M1, M2 and M3.

However, some differences between the two disciplines are worth noting. In economics, the number of authors per publication is a stronger factor than the number of countries. The Normalized Citations Score increases by 5.8% when the number of authors per article increases by one, while the number of citations increases by 1.1% when the number of countries involved in the publication increases by one. In management both number of authors and number of countries, have similar coefficients (M3). Normalized Citations Score increase by nearly 3% when the number of authors or countries involved in the publication increases by one.

The country of journal and citation level

For both disciplines, the country of journal has a significant impact on citations. Thus, the fact that the journal in which the article is published is American or European increases the number of citations, which is not the case for journals published in any other country (that is outside US and EU). It is important to note also that citations increase faster if the journal is American than if it is European. In economics, if the country of the journal's publisher is American, the Normalized Citations Score is 17.6% higher than if it is neither American nor European. The percentage is 10.7 if the journal is European. In management, the percentages for American and European journals are much lower (respectively 8.6% and 4%).

The importance of the impact of the journal

The academic impact of the journal is the variable that most influences the number of citations received by articles. The more the journal in which the article is published has a high impact factor (or well classified by the CNRS), the higher the number of citations. Thus, in economics, citations increase by 29% if the impact factor increases by one. The rate is comparable (26%) in management. Likewise, citations increase as the journal is in the first classes of CNRS categories. However, for economics, the fact that the journal is classified in Category 4 of CNRS (class of least selective journals), has no positive or negative effect on citations. This means that there is no obvious gain from publishing in these journals (compared to journals not classified by the CNRS). This shows that this category 4 is very subjective and does not reflect a consensus within the community on the “quality” of these journals.

Discussion and conclusion

In this paper we have investigated the relationship between gender and citations received by academic papers in economics and management. The most striking results relate to the fact that the author's gender does effect the citations received. We observe that as the proportion of women per article increases, the citations tend to decrease, especially in economics. These results are consistent with previous works that has shown that, across all disciplines, women have less international collaboration than men and that the level of citations is higher for articles written in international collaboration (Larivière et al, 2011; -Salinas et al, 2011). This result is also valid in the natural sciences and engineering as well as in the health sciences (Beaudry and Larivière 2016). In a recent article, Mairesse and Pezonni (2015) showed that, in the case of physics in France, the difference in productivity of female physicists vanishes when other variables are taken into account, particularly inequalities in the chances of promotion of women to positions of full professor, and family commitments. One may wonder if the academic status (lecturer/assistant professor versus full professor) also influences the level of visibility. However, data is lacking to measure such an effect in our sample of nearly 170,000 articles covering two disciplines worldwide. Also, the choice of research objects may be different according to the gender. To take this effect into account and to neutralize it, it would be necessary to normalize the number of citations received by the subfield to which it belongs, which would require the topic of each article to be determined.

Otherwise, the lower impact of articles with a high proportion of women as co-authors may also be due to the fact that women are dealing with topics that have less prestige in the discipline. In field of management, Nielsen et al. (2019) have shown that women are well-represented in social- and human-centered areas of management, while men comprise the vast majority in areas addressing more technical and operational aspects.

Our data also highlight for the first time that the practice of collaboration between genders is quite different in economics and in management. While men publish among themselves in a similar way in both disciplines (about half of the articles are written between men only), we observe that in economics there are much less men-women collaborations (27%) than in management (49%) and therefore more collaboration between women only (21%) compared to only 7% in management. Explanations of such practices would require an in-depth, interview-based qualitative study, but highlighting such differences in collaborative practices is in itself an important result.

Our results also indicate that the visibility of research articles in economics and management is closely linked to the visibility of the journal in which they are published. This was to be expected because we know that there is a Matthew effect related to the journal impact factor (Larivière and Gingras, 2010). A more important result in the current context of bibliometric evaluation of research is the weight of American journals in the visibility of research articles both in economics and management. Indeed, if the journal is American, the citations to the articles will nearly double compared to a journal is European. It is likely that the important role of US journals (as the country of publication of the journal) in determining publication visibility as measured by citations is related to the fact that the WoS database (just like that of SCOPUS by elsewhere) has a strong Anglo-Saxon bias (Gingras and Khelfaoui, 2018). It remains true, however, that researchers' evaluations are, in fact, based on these databases. Our results are therefore all the more important as they may in turn influence the future publication practices of scholars in order to improve their "score" of citations.

Abstract

Web of Science (WoS) and Scopus serve similar functions to the academic community as bibliometric databases, however their content and coverage is known to vary due to their owners' different business philosophies. In this paper, we investigated the impact of the differences in content and coverage between WoS and Scopus on citation-based bibliometric indicators. We calculated the excellence rates for ten countries and the sectors of the German science system to examine the macro-level effects of the differences. We then examined the impact at the micro-level by comparing the normalised citation counts between databases for the publications indexed in both WoS and Scopus by OECD discipline, using German publications from 2009 as an example. We found that WoS "favoured" base research as German sectors in this domain received higher citation-based impact values than in Scopus, while sectors that focused on applied research performed better in Scopus. WoS and Scopus apparently constitute two different resonance chambers and consequently the same content, given its orientation towards applied or base research, will receive a diverging citation-based impact value. Researchers need to consider these differences in focus when selecting a database for bibliometric analyses.

Background and purpose

Web of Science (WoS) and Scopus are both subscription-based databases of multidisciplinary bibliographic information that were developed to provide similar services to the scientific community, that is: to enable retrieval of relevant primarily scientific publications, to identify key journals, papers, authors, or institutions, and to facilitate bibliometric analyses. However, Clarivate Analytics and Elsevier, as owners of WoS and Scopus respectively, fundamentally differ in their business models, which influences the results of analyses using each database. Clarivate Analytics maintains that WoS will sufficiently capture the majority of important research simply by indexing the key journals in each discipline (Testa, 2018). As such, only approximately 10% of the 3,500 journals assessed for indexing in WoS each year are accepted into the 3 top-tier indices – Science Citation Index Expanded (SCIE), Social Science Citation Index (SSCI), and Arts & Humanities Citation Index (A&HCI; Testa, 2018). Conversely, Elsevier intended that Scopus should contain the largest number of records possible and so indexes 30%-70% of the approximately 25-250 journals assessed in any given month (Elsevier, 2017). As a result of their differing business models, WoS had indexed over 20,900 journals as of February 2019 (Clarivate Analytics, 2019) while Scopus had indexed more than 21,950 journals in the latest figures from August 2017 (Elsevier, 2017), with approximately 600 journals added each year since then (Elsevier, n.d.). This also translates to Scopus adding substantially more documents per year, although a large subset of publications are indexed in both databases, as can be seen in Figure 1.

These different business philosophies between Clarivate Analytics and Elsevier have implications for the content of the databases and the outcomes of analyses using them. While differences resulting from the variations in coverage between the databases have been studied extensively (e.g. Mongeon and Paul-Hus, 2016; Aman, 2016), the consequences for bibliometric indicators have mainly been studied in the context of assigning journals to disciplines (Donner, 2016; Wang and Waltman, 2016). Only recently in a case study on information retrieval, Bar-Ilan (2017) linked the differences in coverage to differences in citation counts. This study highlighted that a greater coverage not only increases the included publications of any entities to be analysed, but also increases the overall coverage and therefore alters the environment for any citation-based evaluation of scientific impact of the entities. Further, the changes in the overall coverage and in the coverage of an entity's publications might not be equivalent, but might result in either beneficial or adverse effects for the analysed entities.

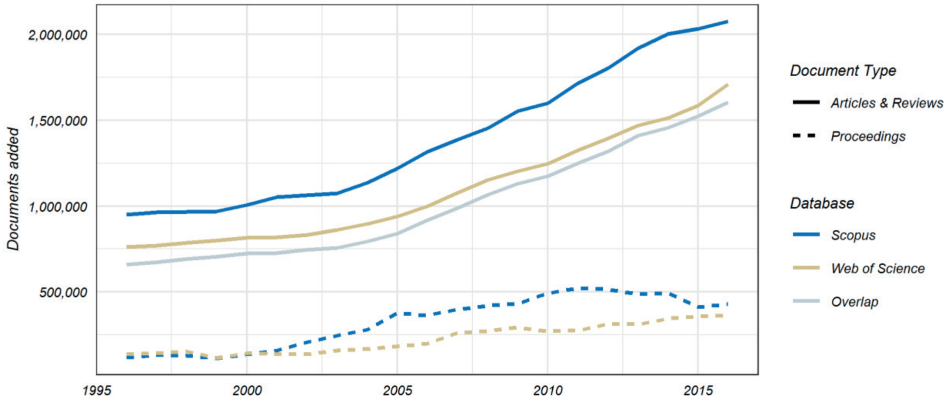

Figure 1. The number of articles and reviews and proceedings indexed in Scopus and WoS, and the overlap – the number published in both databases – annually between 1996 and 2016.[1]

That said, the bibliometric indicators currently commonly applied to gauge this citation-based scientific impact are mostly size-independent and implement this relative approach by relating a publication to a specific environment of similar publications. Due to differences in coverage, WoS and Scopus apply different environments to appraise the same publication, which is one driver of potential macro-level differences between the databases. The impact of different environments on the valuation can be measured by analysing the so-called "duplicated" publications covered jointly in both databases and comparing the database-specific valuation of these publications.

This is because the core differences between both databases consist of the respectively exclusive content. That is to say, any differences in the valuation of the same content result from differences in the respective environment, i.e. the exclusive content. Hence a comparison of the diverging valuation of the same content does not inform on the content itself, but on the exclusive content causing any differences and therefore the databases themselves. Therefore by understanding the deviations at the micro-level from general patterns observed between the databases at the macro-level, we not only explain these abnormalities, but en passant learn about any general difference in the coverage-based "character" of the databases which can facilitate a purposeful, instead of opportunistic, choice of a particular database to satisfy a particular research or evaluation end.

[1] The number of documents added to each database annually was calculated from the databases maintained by the German Competence Centre of Bibliometrics (http://www.bibliometrie.info). The method of determining the overlap in publications indexed in both databases is as described in the Methods section, however without restricting to German authors.

As such, here we examine two research questions. First, what are the macro-level differences in citation-based impact values between the WoS and Scopus databases, and secondly can the cause of the macro-level differences be revealed by comparing individual "duplicate" publications.

Method

The data included in the following analyses are document types 'article' and 'review' (jointly referred to as publications hereafter) published in journals for the relevant publication years. Data were extracted from the Scopus and WoS (SCIE, SSCI and A&HCI indices) databases maintained by the German Competence Centre of Bibliometrics. Fractional counting was used to assign publications to countries or sectors based on each author's reported institution. A citation window of 3 years was used for citation-based indicators. Self-citations have not been excluded.

We first calculated excellence rates to gauge the impact of the differences between the databases at the macro-level of countries and sectors of the German science system. Excellence rates, also known as Highly Cited publications or PP(Top10), are the share of publications belonging to the 10% most highly cited publications in each discipline. We calculated annual excellence rates from 2007 to 2015 based on citations from WoS and Scopus for ten countries with high levels of academic output, and the six German research sectors: Universities of Applied Sciences, or "Fachhochschulen" (FH); Helmholtz Association of German Research Centres with its focus on research infrastructure (HGF), universities (UNI); Frauenhofer Society in applied science (FhG); Max-Planck Society in basic science (MPG); and Leibniz Association that connects basic and applied science (WGL). We used the method described by Waltman and Schreiber (2013) to proportionally assign publications on the 90th percentile threshold to achieve exactly the top 10% most frequently cited publications.

To gain insight into the cause of any macro-level differences observed, we analysed how the same content is evaluated by both databases. As a case study, we identified duplicate publications, i.e. publications indexed in both WoS and Scopus, published by authors in Germany in 2009 and calculated the database-specific valuation of these publications. Publications indexed jointly in WoS and Scopus were identified by comparing hash values on a subset of the available metadata strings. Fractional counts of publications were then aggregated to the OECD Fields of Science and Technology disciplines using the database providers' official mappings to convert the respective database-specific classification to the OECD classification. Items in Scopus' 'multidisciplinary' category have been excluded as this category is not mapped to any OECD category. Also, a small proportion of items unclassified in WoS were also excluded. Due to differences in the mappings of the database providers' classifications to the OECD classification, some duplicated publications might be assigned to different disciplines and are consequently included in the databases' discipline-specific shares of exclusive publications.

We then normalised every duplicated German publication from 2009 in the two environments defined by the exclusive publications. In detail, we computed for every duplicated article i affiliated to a German address in 2009 the ratio

$$\frac{obtained\ citations_i^{(s)}}{expected\ citations_i^{(s)}}, \qquad (1)$$

where s denotes the source of citation and expected citations counts, i.e. WoS or Scopus. Expected citations were computed as the mean number of citations received by articles from

2009 in the three-year post-publication period 2009-2011 that were assigned to the same OECD discipline.

By varying s we obtain a separate citation-based valuation of a duplicated German publication i. Hereby the variation in obtained citations and expected citations could differ, because the exclusive share of publications by each source s might have a varying effect on the general citation level in a discipline expressed in the expected citation counts and the particular impact of a publication i in that context, which might be stronger or weaker than the change in expected citations. Indeed differences in the change of obtained and expected citations facilitate changes in the valuation of publication i, as a uniform increase (or decrease) in obtained and expected citations would not change the ratio and the resulting valuation of the respective publication would stay constant.

Finally, given equation (1), we individually contrasted every duplicated 2009 German article with its corresponding expected citation count, and calculated the percentage of duplicated German articles with difference Δ in normalised citations $norm.\ cit.$ based on

$$\Delta\ norm.\ cit. = \frac{obtained\ citations_i^{(Scopus)}}{expected\ citations_i^{(Scopus)}} - \frac{obtained\ citations_i^{(WOS)}}{expected\ citations_i^{(WoS)}}.$$

Results

The excellence rates for the selected countries are depicted in Figure 2, and show that differences are evident between the databases at this macro-level. For example, the Netherlands and Italy clearly benefited from the use of Scopus, while for China higher impact values were observed in WoS.

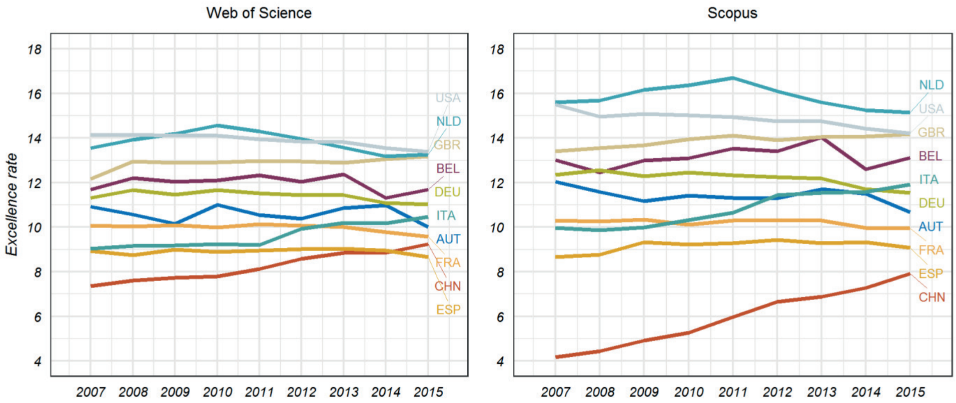

Figure 2. The excellence rates of selected countries between 2007 and 2015 calculated based on publications indexed in WoS (left panel) and Scopus (right panel).

Figure 3 likewise illustrates the excellence rates of the German research sectors. Similar effects to Figure 2 can be seen: while the MPG maintained a relatively high and stable citation-based impact in WoS, in Scopus it declined since 2009. At the same time we might identify a level shift in the impact of the FhG, as its impact was constantly and relative to all other sectors higher in Scopus than in WoS. It is also apparent that the largest effect of the database choice was a uniform level effect in which nearly all entities analysed in Figures 2 and 3 found their citation-based scientific impact was higher in Scopus than WoS. However, as seen, some entities benefit (or lose) relative to other entities from a particular choice of a database.

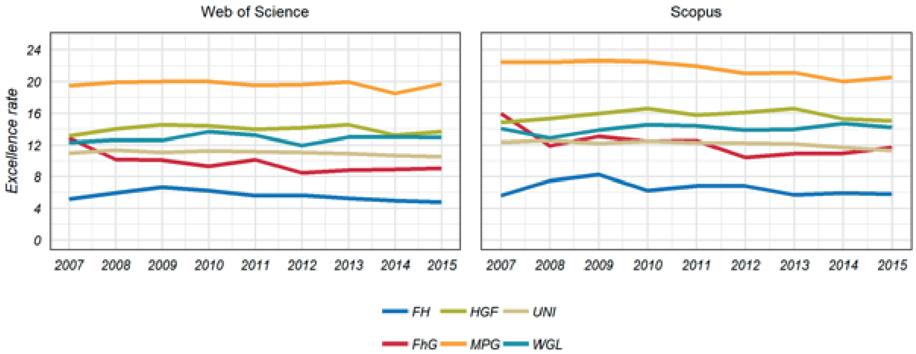

Figure 3. The excellence rates of sectors of the German science system between 2007 and 2015 calculated based on publications indexed in WoS (left panel) and Scopus (right panel).

We sought insight into the cause of these macro-level differences by examining the number of duplicated German publications and contrasting their citation-based values between the databases to observe the particularities induced by the databases' respective exclusive publications. Figure 4 presents the number of overlapping publications and the exclusive publications indexed in only one of the two databases by OECD disciplines. A strong focus on natural sciences and medical and health sciences can be observed. The share of more application-oriented engineering and technology sciences was lower, still, they maintained a substantial share of indexed publications. On the contrary, relatively few publications were indexed for agricultural sciences, social sciences or humanities.

Comparing the distribution of duplicated publications with the exclusive publications, we observed few differences. In terms of publication numbers also, the natural sciences and medical and health sciences had by far the highest share of exclusive publications, the engineering and technology sciences obtained a lower share, and agricultural sciences, social sciences and humanities the lowest share. Furthermore the share of additionally indexed publications in Scopus exceeded in nearly every discipline the exclusive share of the WoS by a wide margin. While, for example, around 2.25 million articles and reviews were assigned to the discipline *Clinical medicine* in both WoS and Scopus for the years 2007 to 2016, Scopus listed another 3.25 million records in this category, while WoS added less than 0.5 million additional records to this particular category. In addition Scopus indexed another 2.25 million records in the category *Other medical sciences*, which does not exist in the WoS mapping. Consequently, Scopus held a much larger number of articles and reviews in the OECD field *medical and health sciences*, a higher-level agglomeration of all medical and health-related OECD disciplines, than WoS and this observation also holds for all other OECD fields.

In general the additional share of publications indexed in Scopus mimicked the distribution of the overlap, adding proportionally more publications by discipline. The numbers of exclusive publications of the WoS were smaller in magnitude and more evenly distributed, at least among the natural sciences, medical and health sciences and engineering and technology. Exclusive publications in agricultural sciences, social sciences and humanities were hardly detectable. The exceptions to these observations were mostly of the residual classes *Other* * and occasions in which mappings do not make uniform use of a certain OECD discipline. In general the corpus of publications indexed by WoS hardly diverged much from the corpus of duplicates, while Scopus presented a much larger corpus and deviated proportionally from the overlap.

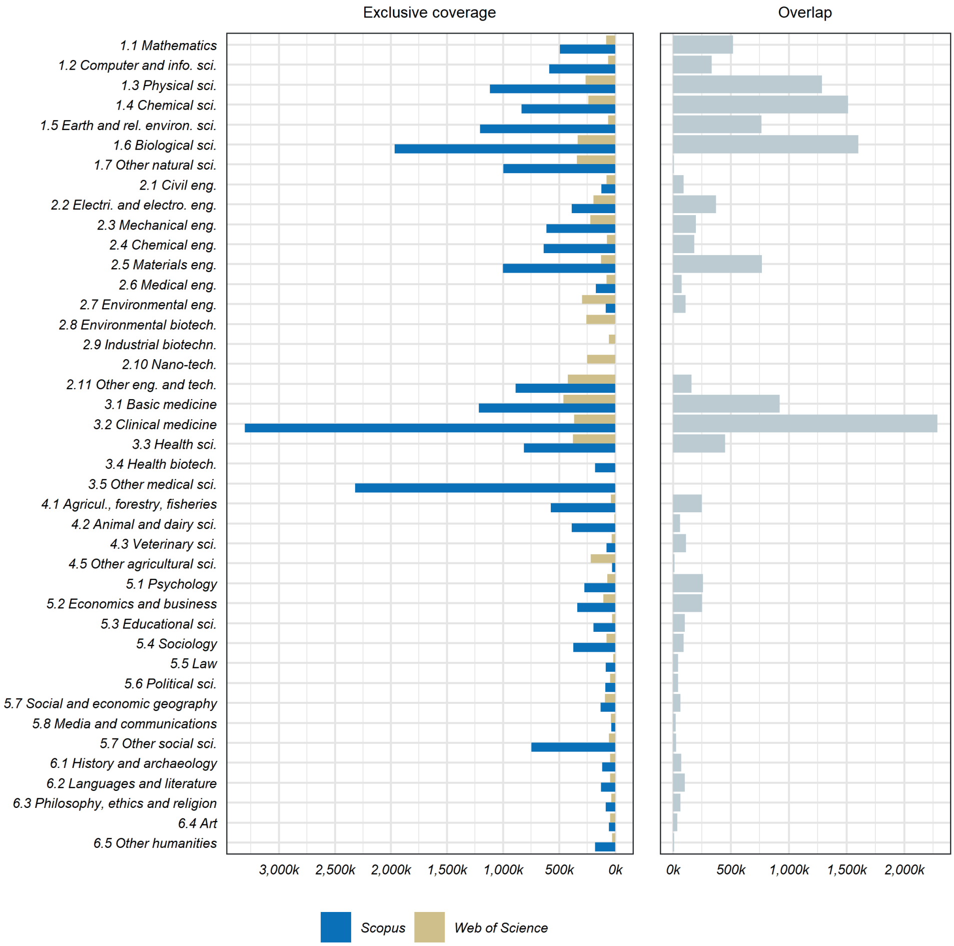

Figure 4. The number of articles and reviews exclusive to Scopus and WoS (left panel), and the number indexed in both databases (right panel) by OECD discipline for the years 2007-2016.

We then compared absolute citation counts and expected citation counts from the WoS and Scopus, as presented in Figure 5. In both graphs there is a strong positive correlation underlining findings, that in general both databases presented a fairly similar picture of national bibliometric evaluation. However some publications obtained more (or fewer) citations in Scopus than postulated by the otherwise linear relation. Also the expected citations of the mapped OECD disciplines followed a clearly positive correlation, although most disciplines possessed a higher expected citation count in either WoS or Scopus than postulated by the linear relationship. These deviations in the obtained or expected citation counts from the mean line caused a non-uniform change in the ratio of equation (1) and consequently a different valuation of German publications in the respective setting.

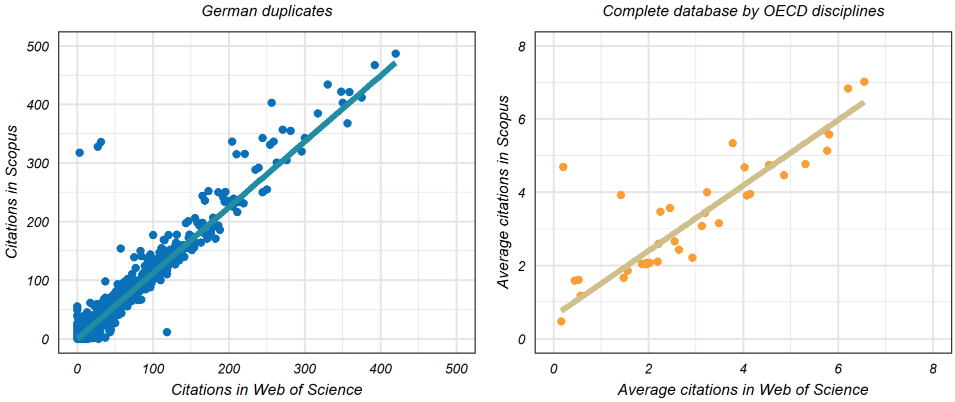

Figure 5. The number of citations for duplicated 2009 German articles in Scopus and WoS (left panel), and the average number of citations by discipline from each database (right panel).

We explored any accruing discipline-specific deviations from the linear trend in Figure 6. To ensure the sample size of publications for a discipline is sufficiently robust for interpretation, we present results for the 19 OECD disciplines with more than 400 duplicated articles affiliated with a German institution in 2009. The difference in raw citation counts is depicted by the blue bars, the mean difference in raw citations is the orange dotted line, and the dark yellow line shows any difference in the expected citation counts. More than 40% of such publications in the OECD discipline *Economics and business* obtained exactly the same number of citations in both databases. Twenty percent of German duplicates in *Economics and business* received one additional citation in Scopus. While in all disciplines the largest share of publications obtained exactly the same number of citations, we also consistently found a right-skewed distribution, in which the aforementioned German publications received in general more citations in Scopus than in WoS. The orange dotted lines depict the mean of these differences and consequently summarise the distributional effects in the blue bars in a single number. By comparing disciplines it might be noted that Scopus favoured German publications in raw citation counts in some disciplines more than in others. Duplicated German publications in *Clinical medicine*, *Economics and business* or *Computer and info. science* seemed to benefit especially from Scopus, while duplicated German publications in *Veterinary science* obtained few additional citations in Scopus.

Any difference in the raw citation count of a duplicated publication represents an altered standing of these duplicated publications in the different environments. General changes in the environments are expressed via differences in the expected citation counts, which are depicted via the dark yellow line in Figure 6. In general these changes in the expected citation counts seemed less pronounced and were sometimes even negative. In any case the additional, exclusive publications by Scopus altered the expected counts because they differ structurally, e.g. in citations over time or between disciplines, citations to non-indexed publications or different citation potentials due to longer or shorter reference lists, from the overlapping set of publications. Via these general changes in expected counts, as well via changes to the raw citation counts of duplicated German publications, the content exclusive to each database defines differences in the national bibliometric evaluation of any analysed entities.

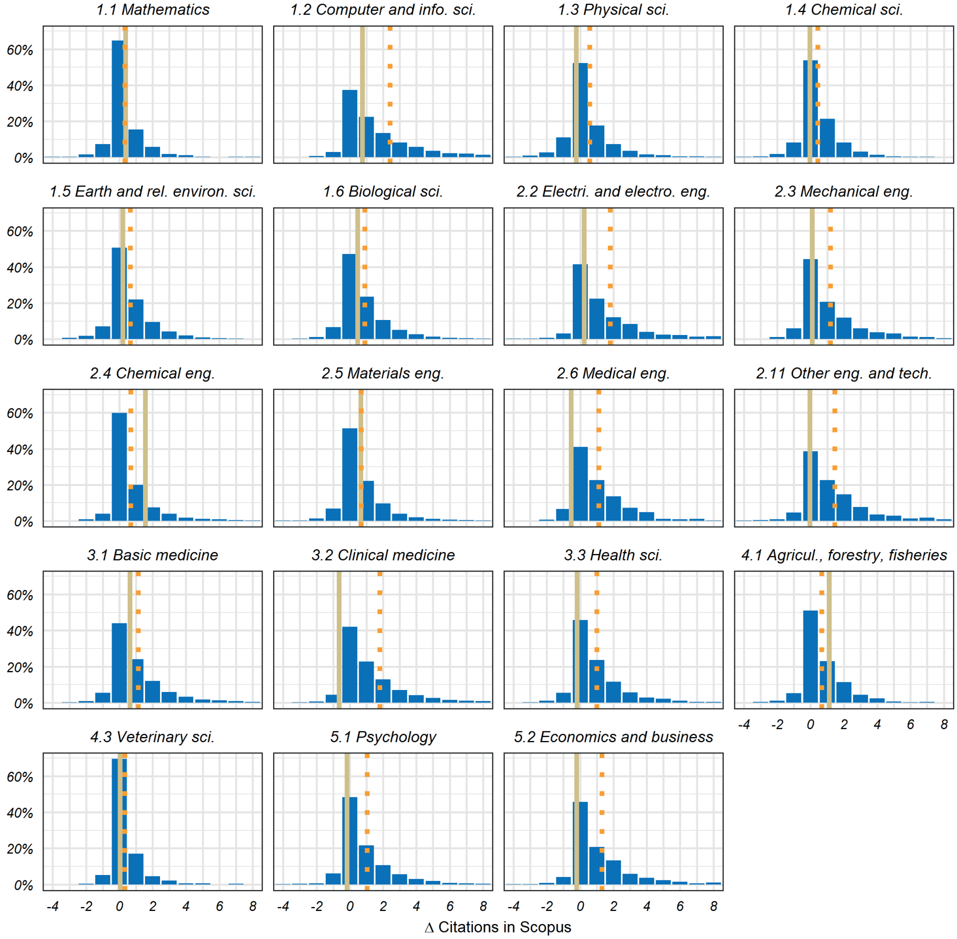

Figure 6. The difference in raw citation counts (blue bars), mean difference in raw citations (dotted line), and difference in expected citation counts (dark yellow line) between WoS and Scopus by OECD discipline.

The distribution of the percentage of duplicated 2009 German article with difference *Δ* in normalised citations $norm.\ cit.$ between databases, as denoted by the blue bars, is depicted in Figure 7. Accordingly more than 60% of German duplicated articles in *Veterinary science* found their normalised citation impact altered in the range of -0.2 to 0. The blue dotted line indicates the mean of this distribution of differences. As to be expected by Figure 6 the mean difference was positive for most disciplines. Duplicated German articles in the discipline *Agriculture, forestry, fisheries* observed on average the most severe negative effect on their citation-based impact stemming from the use of Scopus and its set of exclusive publications. This might also be seen in Figure 6, where the average in additional raw citations for publications in this discipline was outrun by the change in expected citation counts. The same observation also holds for *Mathematics* and *Chemical eng.*, while articles in most other disciplines observed a positive average effect in line with the higher shares in the German excellence rate reported for Scopus than WoS in Figure 2.

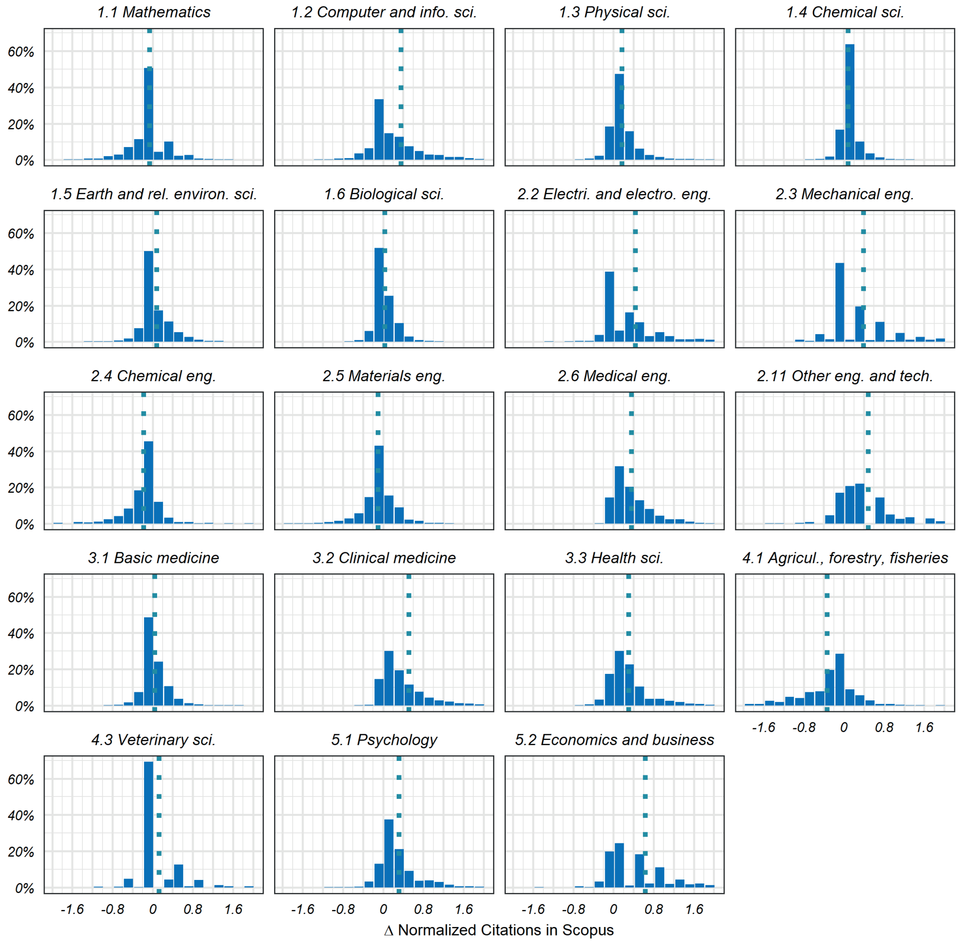

Figure 7. The distribution of duplicated German articles with difference Δ in normalised citations by OECD discipline.

The publication level rationale for the increase in the excellence rate for Germany can be observed in Figure 8. The top panel shows the distribution of $\Delta norm.cit._{(i)}$ for every duplicated 2009 German article. The 40%-60% quintile, depicted in the darkest blue shade, starts right above the zero line of no effect and almost reaches up to the 0.1 line. Given that a normalised citation count of 1 for a publication is commonly interpreted as exactly reaching the discipline-specific citation expectation an increase of 0.1 might be interpreted as 10% increase in this indicator. Consequently the 20% most strongly affected German duplicates improved on their normalised citation impact by over 25% in Scopus, while the 20%-40% quintile of affected German publications had reductions on their normalised citation impact of -5% to zero. Consequently the distribution is skewed to the right allowing duplicated German publications to obtain on average a higher normalised citation impact in Scopus than WoS.

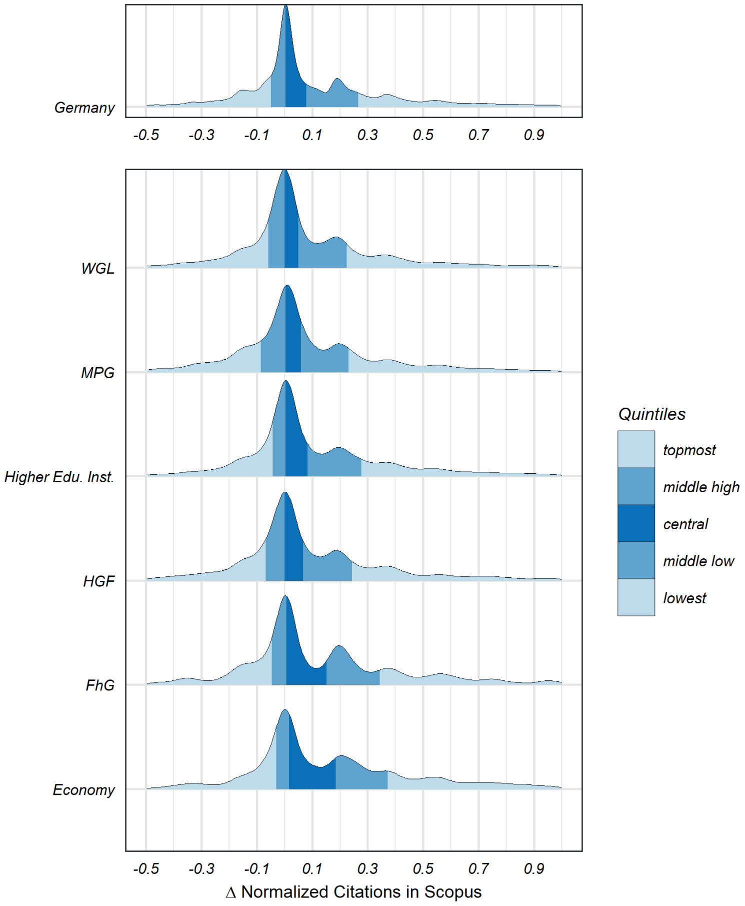

Figure 8. The distribution of $\Delta norm.cit._{(i)}$ for every duplicated 2009 German article (top panel), and by research sector (bottom panel) with quintiles denoted.

The lower panel of Figure 8 subdivides the duplicated 2009 German articles by the aforementioned sectors. In general all sectors showed similar distributions to the national one. The distribution of the Higher Education Institutions sector, which is dominated by German universities, but also includes universities of applied sciences or specialised schools/colleges, most closely resembled the national distribution, as these institutions are responsible for the largest share of German publications. Surprisingly the MPG obtained the weakest effect on increased normalised citations of all sectors, although its excellence rate clearly outperformed all other sectors. On the contrary the strongest effect was observed for the publications affiliated with the German business sector (denoted by "Economy") and the FhG, which according to their excellence rate, found themselves on the lower half of citation-based impact assessment.

Discussion

The purpose of this study was to first gauge the magnitude of macro-level differences in citation-based impact values between the WoS and Scopus databases due to differences in their content and coverage, and secondly determine the origin of these differences through a comparison of the valuations of publications indexed in both databases. With regard to the macro-level differences, in calculating excellence rates for countries and German research sectors, we found that nearly all of the entities examined experienced a uniform level effect with higher impact values in Scopus than WoS, although some entities gained or lost relatively to others dependant on the database. Further, a comparison of the citation-based valuations of duplicate publications between databases revealed the macro-level differences occur as the databases each “favour” a domain of research.

For example, the FhG and the German business sector might be distinguished by their missions, respectively intrinsic needs, from other German sectors by their greater orientation towards applied research, translation or technology. Their publications, as observed in Figure 3, lag behind most other sectors in their overall citation impact in WoS. But at the same time their duplicated publications indexed in WoS and Scopus observed the highest gains in Scopus among all other sectors. Consequently the resonance of these duplicated publications stemming from an applied research environment is higher in Scopus than in WoS. Hence the particular selection of exclusive publications by Scopus shows a stronger interest in applied research, translation and technologies and therefore ultimately the Scopus database itself might be differentiated by its stronger focus on applied research, translation and technologies.

On the other hand, the MPG excels in WoS citation-based scientific impact, as given its mission it focuses nearly exclusively on base research. However, its duplicated publications gain least by switching to Scopus. Further, its Scopus-based excellence rate in Figure 3 has constantly declined since 2009 despite the steadily increasing difference in indexed publications seen in Figure 1. The number of publications exclusively indexed by Scopus grows increasingly in the same timeframe, as the excellence rate of the MPG decreased, i.e. while Scopus increasingly differentiates from WoS and establishes its own “character”, the base-research-orientated MPG seems to increasingly lose from this differentiation while its excellence rate in WoS stays constant. Consequently WoS seems to focus more on relatively highly cited base research.

WoS and Scopus apparently constitute two different resonance chambers and consequently the same content, given its orientation towards applied or base research, will receive a diverging citation-based impact value. WoS focuses on relatively highly cited base research and will value any such research higher, while Scopus – with its stronger focus on national or regional journals which may seek to answer applied research questions in the local context context – seems to add an outer ring of applied research, translation or technologies and will appraise respective publications higher. It is up to the researcher then to decide which database best suits their project, given their research or evaluation objectives.

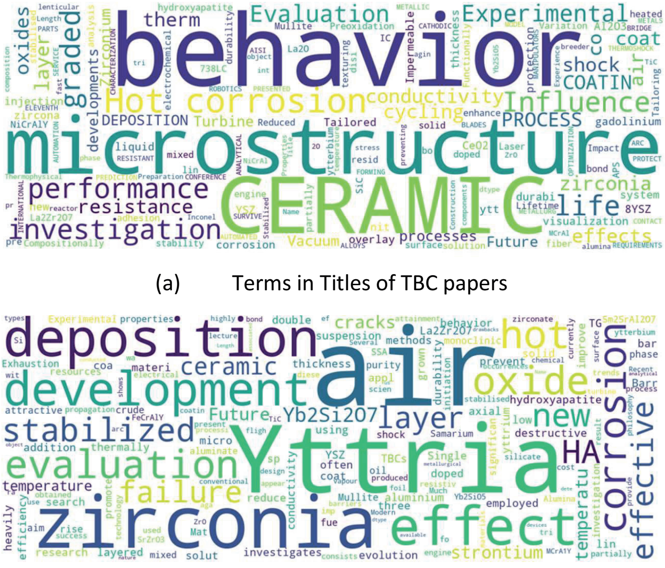
Abstract

Thermal barrier coating (TBC) systems reduce the temperature of the metallic substrate of modern gas turbines, resulting in improved component durability and increased efficiency. This study examine the research publications and patents on thermal barrier coating in Scopus and USPTO patent database, respectively, during the period 1981-2018. Bibliometrics analysis reveal the developments in country and institution contribution to thermal barrier coating research as well as the trends in topics evolution and technology advancement. Results show that USA, China, Germany, Japan, India and United Kingdom are the top countries in thermal barrier coating research, and the Chinese Academy of Science, Beihang University, Forschungszentrum Juelich, NASA Glenn Research Center and Deutsches Zentrum fuer Luft- Und Raumfahrt are among the leading institutions that have high scholarly research output during 1981-2018. While USA dominated the TBC publication output during 1981 to 2010, China takes the lead after 2011 on TBC papers, and India took over Germany to become the third leading country on TBC research in 2018. The terms of the titles, keywords and abstracts of the publications, mapped visually using the VOSviewer reveal the progress of thermal spray technology. Results show that atmospheric plasma spraying (APS) and electron beam physical vapour deposition (EB-PVD) are well-established deposition techniques for TBC coating preparation, and plasma spray physical vapour deposition (PS-PVD) and low-pressure plasma spraying (LPPS) are two new emerging deposition techniques in TBC research. The journal papers cited by patents have low correlation to the highly cited papers in Scopus.

Introduction

Thermal barrier coatings (TBC) are refractory and thermally insulating ceramic coatings deposited on substrates to protect components from high temperatures (Shiembob and Hyland, 1979; Miller, 1987; Goswami, Ray & Sahay, 2004; Guo, Gong & Xu, 2014). TBCs are primarily a two layer system consisting of a ceramic top coat layer of yttria partially stabilized zirconia (YSZ) and an alumina forming bond coat layer, primarily of NiCoCrAlY or NiAlPt based compositions (Guo, Vassen & Stover, 2004; Padture, Gell & Jordan, 2002; Darolia, 2013; Busso, Wright & Evans, 2007). Atmospheric plasma spraying (APS) and electron beam physical vapour deposition (EB-PVD) are the two main processes in preparing TBCs (Padture, Gell & Jordan, 2002; Bose & DeMasiMarcin, 1997). TBCs are widely employed to lend thermal protection to metallic surfaces in aeroplane engines and gas turbine parts. Over the years, the TBCs have gradually developed from merely insulating layers to more complex designs. By considering factors such as heat flux, heat transfer coefficients, backside cooling, part geometry and location, coating thickness and its thermal conductivity, higher thermal efficiency is achieved (Golosnoy, Cipitria & Clyne, 2009). New materials (Clarke & Phillpot, 2005; Wang, Lu, Huang & Xie, 2018; Gurak, Flamant & Laversenne, 2018), structures and manufacture processes (He, Guo & Peng, 2013; Bakan & Vaßen, 2017; Fauchais, Montavon & Lima, 2011; Markocsan, Gupta & Joshi, 2017) on TBCs are explored for application in future aeroplane engines. Currently, turbine engine heat-components based on Ni-based superalloys have reached their upper limit of temperature capabilities. Therefore, alternative materials such as SiC(fibre)/SiC ceramic matrix composites (CMCs) are investigated as next generation turbine engine heat-component (Murthy, Nemeth & Brewer, 2008). Environmental barrier coating (EBC) systems deposited on top of CMC components protects the Si-based CMCs from water vapor attack at high temperatures (Suzuki, Sodeoka & Inoue, 2008; Zhang, Zhou & Liu, 2017; Appleby, Zhu & Morscher, 2015). Along with the technology progress is a rapid growth in global research paper output and citation impact on thermal barrier coatings publications. Figure 1 give a Wordle representation of terms used in abstracts and titles of thermal barrier coating publications. This Wordle representation clearly shows that ytrria stabilized zirconia (a ceramic) as the dominant thermal barrier coating material, while new materials like $La_2Zr_2O_7$ is emerging as high temperature coatings.



(a) Terms in Titles of TBC papers

(b) Terms in Abstracts of TBC Papers

Figure 1. Terms in titles and abstracts of thermal barrier coatings

Research papers on thermal barrier coatings over the past 38 years (1981-2018) from Scopus provide an understanding of the global research in this field. The publication data enable analysis of annual scholarly outputs and impact, mainstream journals, leading countries and institutions. Patents published by USPTO on thermal barrier coating related topics are downloaded, and analysed. Special focus placed on the citations of journal papers in patents and the co-relation with highly cited papers on thermal barrier coatings in Scopus.

Method and Data Set

Papers on thermal barrier coatings

Publications on TBC found in Scopus during 1981-2018 are examined using the query “((TITLE-ABS-KEY (“thermal barrier" OR "thermal barriers") AND TITLE-ABS-KEY (coating OR coated OR coatings OR coat)))”. The total number of articles found is 8966. The extracted publications are analysed for countries and researchers (Institutions) collaborations and FWCI (by uploading these papers to SciVal).

Patents on thermal barrier coatings

The USPTO Patent Full-Text and Image Database (PatFT) Quick Search engine is the data source. The searched term “thermal barrier coating” is in “All Fields” and “1976 to present [full-text]” specified as search period. Analysis performed on over 2,940 patents. The abstract and reference citation information for the patents with "thermal barrier coating" in the patent title (around 340 patents) are downloaded for term and reference analysis. The titles, publication year and abstracts of the patents are inserted into the Web of Science publication data template for term analysis.

Journal and Conference Publications on Thermal Barrier Coatings

Leading Countries and Institutions

Figure 2 shows the yearly publications on TBC for the top 10 countries contributing to thermal barrier coatings. USA took the leading position during 1981-2008, while the contribution of China have grown rapidly after 2001, and it became the leading country during the past 10 years. The study of thermal barrier coating in China started in late 1980s on plasma spray TBC. In the mid-1990s, a group of researchers in Beihang University (formerly known as BUAA) set up a lab to carry out research in EB-PVD thermal barrier coatings in order to catch up with the global research frontiers on TBC. As China sets aviation industry as one of its national strategic key industries, strong support from the government poured into aerospace and air transport related research and development areas with several of its national 5-year plans, the research on TBC in China has progress aggressively, as shown in Figure 2. Other top countries include Germany, Japan, United Kingdom and France. India is another rapidly advancing country on thermal barrier coating research.

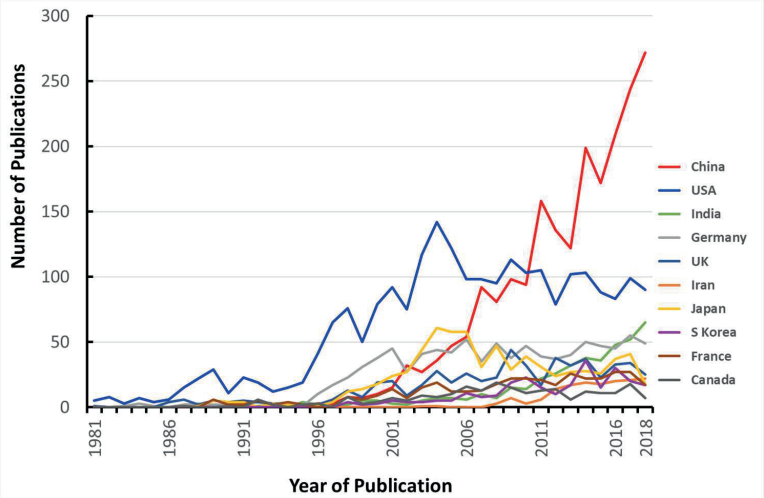


Figure 2. Yearly scholarly output for top 10 countries on thermal barrier coatings.

Among the institutions, German Aerospace Center (DLR), NASA Glenn Research Center are the two leading institutions on TBC research during the period 1996-2005; while the Chinese Academy of Sciences and Beihang University become the leaders in the past 10 years.

Figure 3 shows the 5-year average field-weighted citation impact (FWCI) for the publications on thermal barrier coatings in various subject areas. These subject area categories are high-level SciVal categories. Some papers may be assigned to more than one categories. Yet, this should not affect the results significantly, as the FWCI of each interdisciplinary paper has already count in the effect of different subject area categories. One can find that the FWCI of publications published in recent years generally have a lower FWCI than those published in the past. This reflects the fact that, the effect of thermal barrier coatings research is for the long term. From the first concept of thermal barrier coating in 1940s to the first application teste in the 1970s, it took over 30 years to put the idea into practical use. So past publications on thermal barrier coatings are still quite relevant to contemporary applications, and are highly cited. While publications in materials sciences have a higher 5-year average FWCI before the period 2004-2008, chemical engineering started with a low 5-year average FWCI during 2003-2007, and grew rapidly in the following periods. Compared to materials and structure design which takes a long time, chemical characterization of TBC coatings and combustion science take a much shorter cycle, so that publications in the last five or ten years are more likely get high attentions.

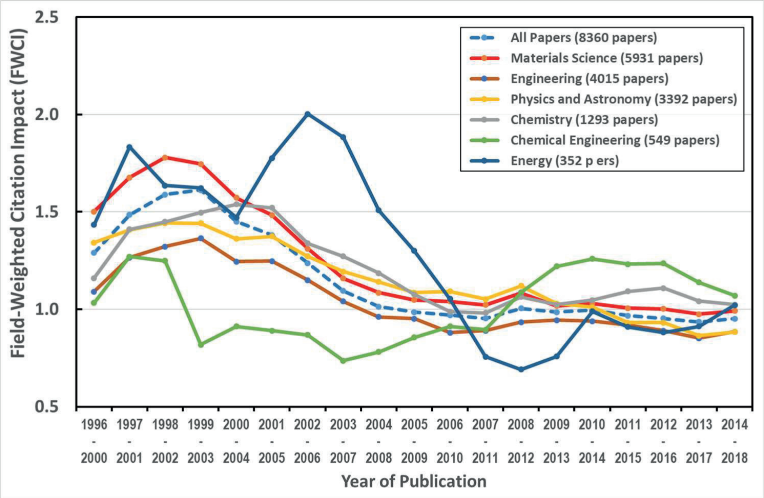

Figure 3. 5-Year Average FWCI for Top 6 Research Areas of Global TBC Research (Data from SciVal, Time Span: 1996 – 2018)

Figure 4(a) and (b) show the trends of country and researchers in TBC and their collaboration networks.

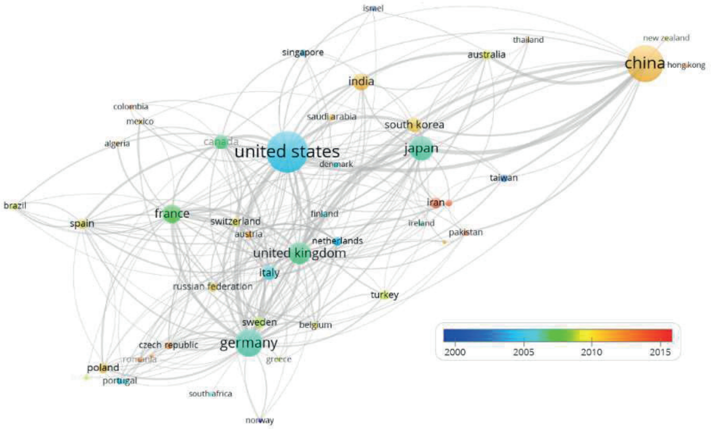

Figure 4(a). Mapping of Contributing Countries and their Collaborations in TBC Research (Total 192 countries, 48 countries with No. of publications > 5)

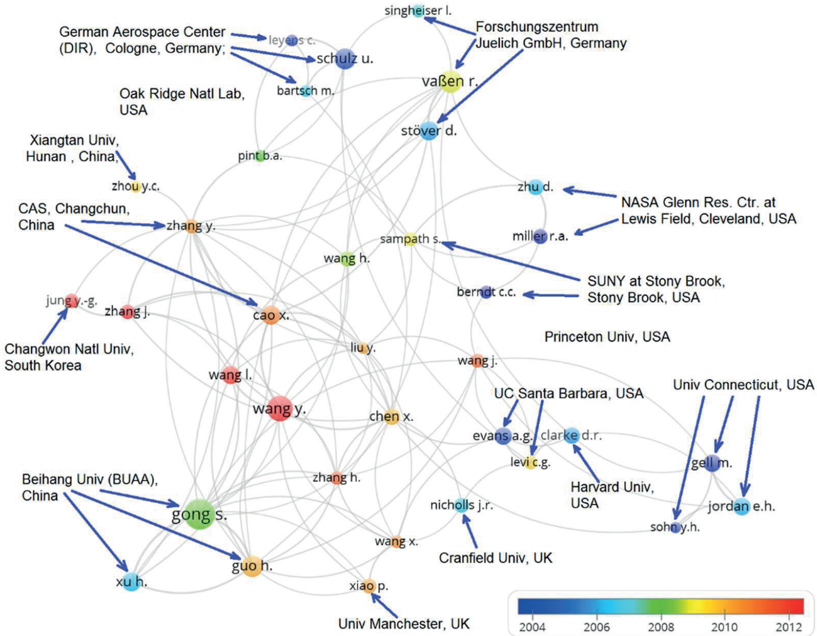

Figure 4(b). Mapping of Researchers and their Collaborations in Thermal Barrier Coating Research (Total 11681 Researchers, 35 researchers with No. of publications > 40)

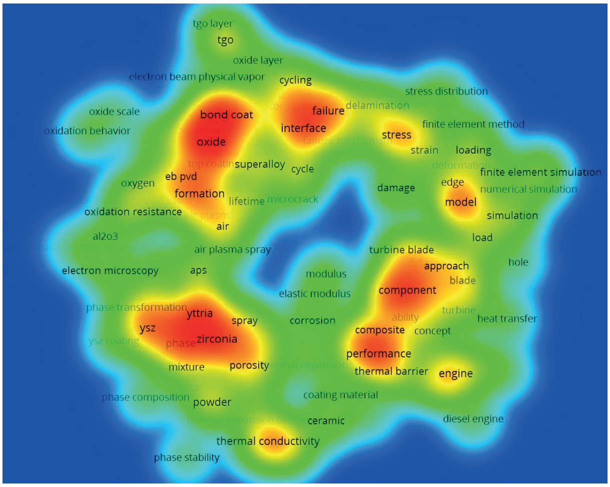
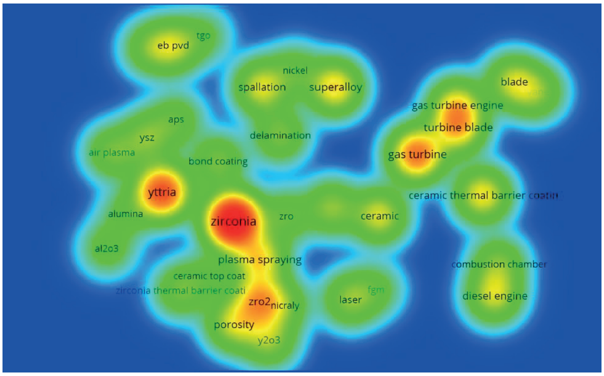
USA and China are the leading countries in different periods, and researchers from German Aerospace Center (DLR), NASA Glenn Research Center, Chinese Academy of Sciences and Beihang University contribute to significant portion of publications on TBC technology. The collaboration map also clearly shows the collaboration of TBCs research between USA, Germany and China or India over the years. Many of the Chinese researchers studied in USA or Germany on TBC technology. These researchers applied the knowledge they learned on their research upon return to China, which helps the rapid development of TBC research in the Chinese institutions.

Mapping of Technical Terms and Institutions

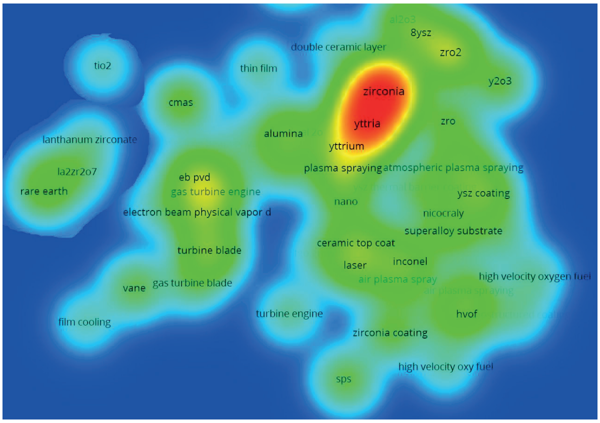
Figure 5(a) and (b) shows the research area trends by mapping the technical terms used in the titles and abstracts in the publications. Selection of terms limited to those that occurred 20 times or more in the year. Terms such as “EB PVD“, “Plasma Spraying”, “YSZ”, “Gas Turbine Engine” can be seen in the maps on the 1981-2000 period, while terms like “Lanthanum Zirconate”, “Rare Earth”, CMAS, “double ceramic layer”, SPS (suspension plasma spraying), HVOF are found in the map for the period 2011-2018, denoting the novel materials, fresh considerations and innovative processing technologies in thermal barrier coatings.



(a) 1981-2018, 85495 terms, Occurrences > 100, 314 terms, 150 selected



(b) 1981-2000, 18057 terms, Occurrences > 25, 207 terms, 35 selected



(a) 2011-2018, 43426 terms, Occurrences > 25, 518 terms, 57 selected

Figure 5. Terms used in thermal barrier coating publications published in Year (a) 1981-2016, (b) 1981-2000 and (c) 2011-2018.

Patents on Thermal Barrier Coatings

Analysis of Patents on Thermal Barrier Coatings

NASA initiates the concept of thermal barrier coating in 1940s, and its first application tested in the 1970s. Figure 6 shows the annual number of patents published by the USPTO on thermal barrier coating related research topics. Figure 6 shows the patents published by the USPTO increase steadily. There is a sharp increase during the period 2001-2003, which is in correspondence with the development of ultra-efficient engine technology by adopting low thermal conductivity TBC and new idea of environmental barrier coatings, i.e., coatings for uncooled silicon nitride (Si_3N_4) series of uncooled turbine blades.

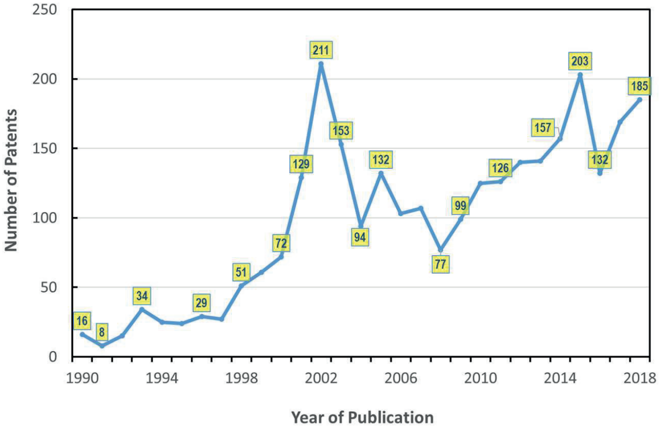


Figure 6. Yearly number of patents published by USPTO on thermal barrier coating related research areas, 1990-2018.

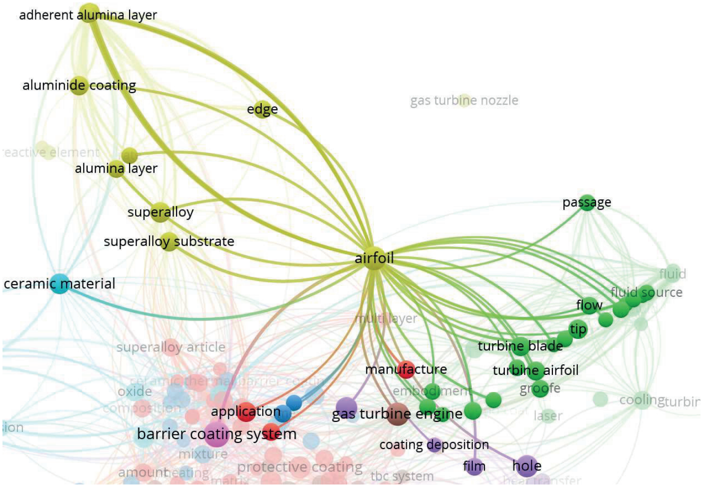
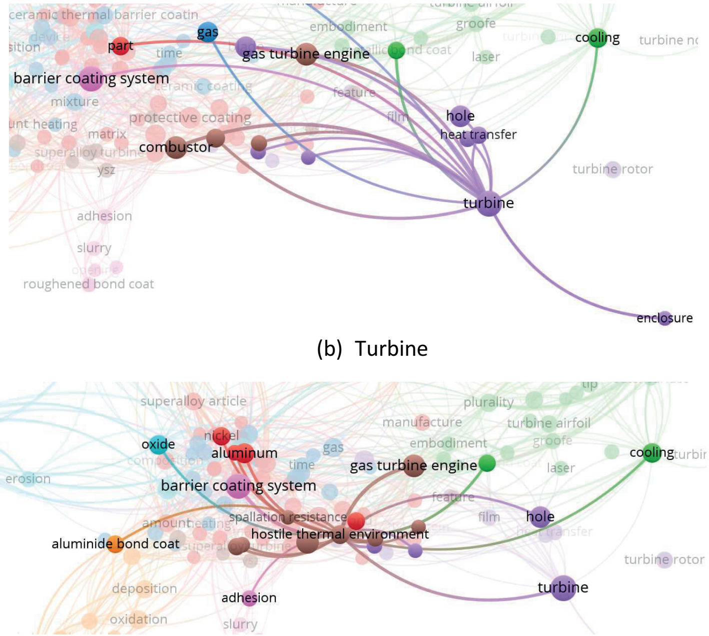
Figure 7 shows an analysis of the terms used in the titles and abstracts of patents published during 2001-2003 by the USPTO on TBC related research topics.



(a) Airfoil

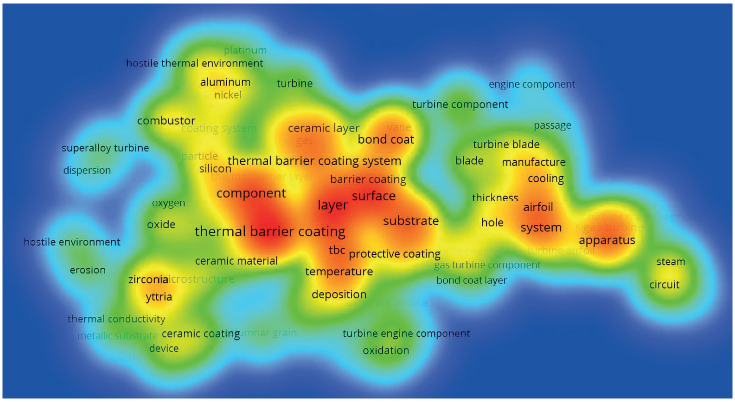


(b) Turbine

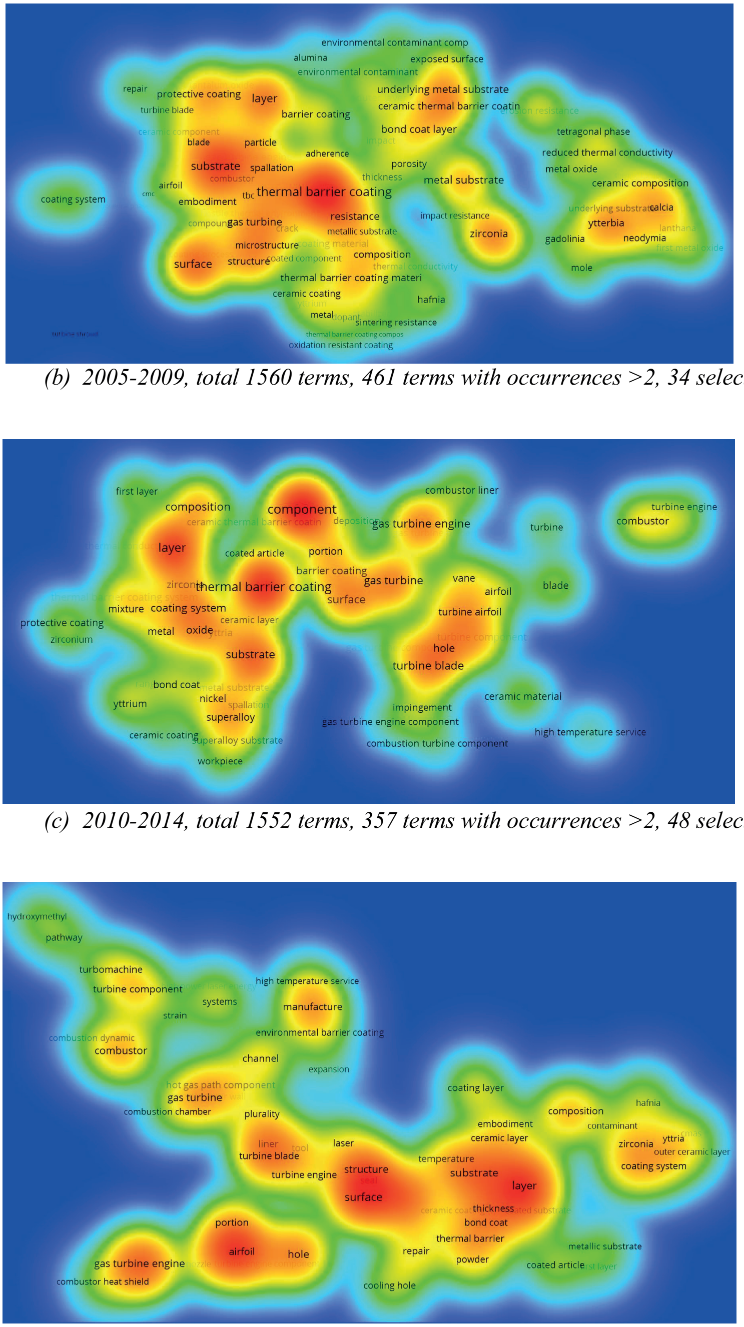
(c) Hostile thermal environment

Figure 7. Term maps for patents published by USPTO on TBC related research areas, 2001-2003.

In order to investigate the trends of patents on thermal barrier coating, the terms used in the titles and abstracts of patents published by USPTO during 2000-2018 are analysed. The term mapping are shown in Figure 8(a) to (d). Terms such as "thermal barrier coating", "Plasma Spraying", YSZ, "Gas Turbine Engine" can be seen during the 2000-2004 and 2005-2009 maps. Correspondingly, terms like "Lanthanum Zirconate", "Rare Earth", CMAS, "double ceramic layer", SPS (suspension plasma spraying), HVOF are found in the maps for the period 2011-2014, and subsequently, "self-healing", "environmental barrier coating" are found in the map for the period 2015-2018, denoting the new materials, new considerations and innovative processing technologies in thermal barrier coatings.



(a) 2000-2004, total 1739 terms, 562 terms with occurrences >2, 77 selected



(b) 2005-2009, total 1560 terms, 461 terms with occurrences >2, 34 selected

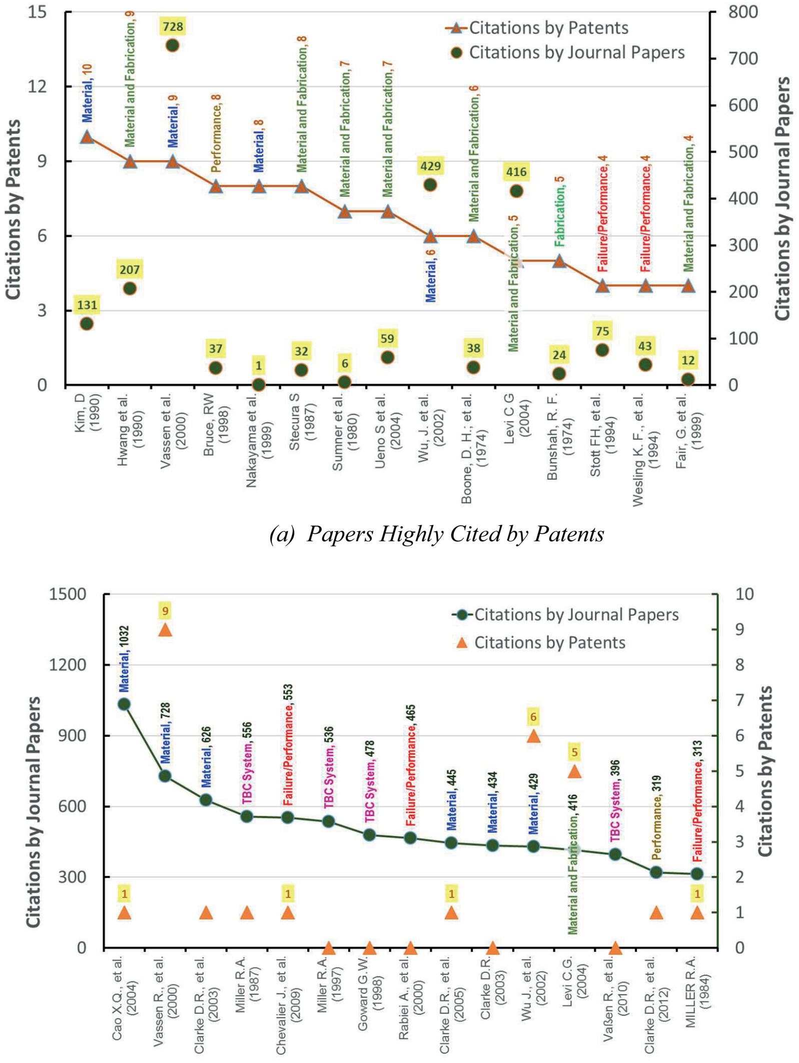
(c) 2010-2014, total 1552 terms, 357 terms with occurrences >2, 48 selected

(d) 2015-2018, total 1309 terms, 300 terms with occurrences > 2, 32 selected

Figure 8. Terms used in thermal barrier coating publications published in Year (a) 1981-2000, and (b) 2011-2018.

Papers on Thermal Barrier Coatings that are Highly Cited by Patents and Journal Papers

In order to ascertain the influence of journal papers on patents, the journal papers cited in patents of thermal barrier coating are studied. More than 400 patents with "thermal barrier coating" in their title are selected, and around 500 papers cited in these selected patents are identified. Figure 9(a) plots a list of the top 15 papers with high citations in patents. Among these 15 papers, only four of them have high (more than 200) journal citations. Conversely, among the top 15 highly cited TBC papers, only three papers received more than one citation by patents, as shown in Figure 9(b). This indicates that topics in patents have low correlation with academic research topics on TBCs.



(a) *Papers Highly Cited by Patents*

(b) *Papers Highly Cited by Journal Papers*

Figure 9. Top 15 Highly Cited Papers by Patents and by Journals.

Academic research interests are significantly broader than industry needs. Many novel ideas reported in TBC papers may not have the requisite potential or relevance to the specifications of the aerospace industry. In addition, most of the work reported in journals may not yet have results that appeal to an industrial application. There are distinctive difference on the topics between highly patent-cited papers and highly journal-cited papers. While highly patent-cited papers are more focused on materials' fabrication and performance, highly journal-cited papers are more focused on TBC system in general and its performance.

Summary

In the past 38 years, the number of research publications on thermal barrier coatings research rose steadily. The USA took a leading position during 1999-2008, and China took over the lead from 2009 onwards, indicated by the rapid rise of publications by Chinese researchers, and showing China's ambition in its aviation industry development. The FWCI of publications in recent years generally have lower values than those published in the past. While publications in materials sciences have a higher 5-year average FWCI before the period of 2003-2007, chemical engineering started with a low 5-year average FWCI during 2003-2007, and grew rapidly in subsequent years. The FWCI trend variances in the TBC research topics reflect the shifting effective phases of research-application cycles of the corresponding research focus. The evolution trends of research topics revealed by mapping of the technical terms in titles and abstracts of the publications shows that new materials like "Lanthanum Zirconate", "Rare Earth"; new designs of coating systems like "double ceramic layer", and new processing technics like SPS (suspension plasma spraying) and HVOF are employed in thermal barrier coatings. These will promote the rapid development of TBC and make it highly relevant in future aircraft engines. Analysis of patent citations of journal papers shows that research topics in patents have low correlation with academic research topics on TBCs. Nevertheless, academic research interests on TBC are broader and based on new ideas on TBC systems and its performance. Most of which have yet to address industry concerns, and far from the final stage of industrial applications.

Has the 2008 Global Financial Crisis a lasting impact on universities and public research institutes in the European Union?

Marc Luwel and Thed N. van Leeuwen

**{luwel, leeuwen}@cwts.leidenuniv.nl*

Centre for Science and Technology Studies (CWTS),
University Leiden, Netherlands

Introduction

2018 marked the 10th anniversary of the 2008 Global Financial Crisis (GFC) followed by a global recession, for most economists the worst disaster since the great depression of the 1930s.

The GFC created in the Eurozone, the 19 EU member states which have adopted the euro as their common currency, an asymmetric shock, affecting particularly the heavily indebted countries Cyprus, Ireland, Greece, Ireland, Spain and Portugal. The result was the Eurozone Crisis. In the aftermath of GFC these countries were unable to refinance their sovereign debt and/or bail out their debt overloaded banks.

Not only in these six Eurozone countries but all over the EU this combination led to a substantial increase in the government debt-to-GDP ratio. To reduce budget deficits, government spending was reduced in the Eurozone. This affected severely the public sector in the heavily indebted countries, but also in countries such as Belgium that was confronted with the near collapse of its three major banks and Italy that had to prop up its banking sector and large firms. With their small open economies the Scandinavian EU member states were also confronted with the impact of the GFC, but the Nordic model turns out to be less vulnerable and more resilient (Gylfason et al., 2010). Of these countries, only Finland is a member of the Eurozone.

In the Eurozone cuts in government spending had also an impact on public R&D expenditures and in particular on the public funding of the higher education sector (EUA, 2011) and public research institutes. A number of authors studied the performance of public R&D funding systems at country level (Lepori, Reale & Spinello, 2018 and references therein). However 10 years after the start of the GFC little work has been done on the impact of the reduction in public funding on the research performance of the higher education sector and the public research institutes.

In the present study, for a panel of eight Eurozone countries and the two Scandinavian EU member states with their own official currency we investigate trends in the publication output of these institutes and the potential existence of causality between funding and output. To tackle these questions models and techniques developed in econometrics are applied on bibliometric data.

The remainder of this paper is organized as follows. Section 2 describes the data that are used in the model. In section 3 the model and the methodology are presented. Section 4 provides the quantitative results and in section 5 their policy relevance and follow up work are discussed.

Data

In most developed countries nearly all basic research is done at universities and public research institutes and to a large extent funded by public authorities. Although these organizations have multifaceted missions, most of the results of their research activities becomes publicly available.

Although they do not cover the total research output papers published in scholarly journals are often used as a proxy for this output. In this paper the proxy is further restricted to the publications in journals covered by the Web of Science (WoS), a bibliographic database produced by Clarivate Analytics. The WoS which coverage has been extended over the last decades, now covers all major journals within the natural and life sciences, medicine and the basic disciplines in applied sciences as well as peer reviewed conference proceedings. However scholarly journals in the humanities and social sciences remain poorly represented with a bias towards those published in English (van Leeuwen, 2013).

For this analysis the data on scientific publications were extracted from the WoS database licensed to the Centre of Science and Technology Studies, Leiden University. This version of the database includes the Science Citation Index Expanded, the Social Science Citation Index and the Arts and Humanities Citation Index. For this study only the publication types 'articles', 'reviews' and 'letters' were taken into account. In the counting scheme the first two publication types received 1 as weight and the letters were weighted as 0.25.

To study the publication output at the level of countries an important methodological issue is the applied counting scheme. An increasing number of journal publications are co-authored by researchers working in different countries (Luukonen et al., 1993; van Leeuwen, 2009). In this paper publications are aggregated at country level applying two counting schemes. The 'whole' counting scheme gives equal weight to all the countries mentioned in the by-line of a publication, is used. An alternative 'fractional' counting scheme allocate to each country a fractional weight based on the number of countries in the by-line (Perianes-Rodriguez, Waltman & van Eck, 2016). For example a publication with two addresses from Belgium, three addresses from Italy and one address from Greece, is counted as one third for each of the three countries. More sophisticated counting schemes have been devised but they are outside the scope of this study.

OECD publishes data on its member states' research funding. These data are produced by these countries using the methodology to collect statistics on research and development described in the Frascati Manual (OECD, 2015).

One of the statistics collected by the OECD is the total intramural expenditure on R&D performed in the national territory during a specific reference period, the Gross domestic expenditure on R&D (GERD). As a proxy for expenditure on research of a country's higher education institutes the component of the GERD incurred by units belonging to the higher education sector, called Higher education expenditure on R&D (HERD), is used. It is the measure of intramural R&D expenditure within the higher education sector.

Similarly, a proxy for the expenditure on research carried out by public research institutes and other governmental organizations is the measure of expenditure on intramural R&D within the Government sector during a specific reference period. This component of the GERD is labelled Government Expenditure on R&D (GOVERD).

To correct for differences in inflation rate and purchasing power among countries the data on the HERD and the GOVERD are expressed in 2010 US $ constant prices and purchasing power parity (PPP).

In the OECD Main Science and Technology Indicators database these data are publicly available on an annual basis (see: https://stats.oecd.org/). For some countries and some years there are missing values. For example for Sweden only biannual data on HERD and GOVERD are available for the later part of last century. In this study the missing values are estimated using linear interpolation. At the moment the study was made the 2017 data on HERD and GOVERD were not yet published; they were estimated using an extrapolation based on the 2015 and 2016 values. The sum of the HERD and GOVERD, further research expenditure, was used as a proxy for the public expenditure on research in the combined higher education and the government sector (Aksnes et al., 2017).

Methodology

In this study time series analysis is applied on research expenditure and publication data of countries. In this section concepts and techniques used in this study are succinctly described with the appropriate references to relevant literature.

The panel countries

For this study, eight Eurozone countries were selected based on the degree of severity of the impact of the GFC. These countries can be classified in three groups:

- Group 1: Countries strongly affected by the GFC: Ireland (IE), Greece (GR), Spain (ES), Portugal (PT);
- Group 2: Countries with severe problems in their banking sector: Belgium (BE) and Italy (IT);
- Group 3: The countries, more mildly affected by the GFC: Netherlands (NL) and Finland (FI).

To complete the panel the two other Scandinavian EU member states were added: Denmark (DK) and Sweden (SK). These two countries were also only mildly affected by the GFC.

Statistical tools

The data are analyzed with the statistical package EViews (version 10) developed by IHS Markit Ltd mainly for time-series oriented econometric analysis. The EViews 10 User's Guide I and II (EViews 10, 2017a, 2017b) provides a detailed description of the models and tests applied in this study and the relevant references to the scientific literature.

Stationary and non-stationary time series

The data on expenditures and on publications are both univariate time series, a sequence of measurements of the same variable indexed in time order. In this study, the data are available per annum.

In time series analysis a distinction is made between stationary and non-stationary series (Brockwell & Davis, 2016). For a stationary time series, the mean, variance and covariance are not a function of time. In the presence of a deterministic trend, i.e. a consistent directional movement, the time series is called trend stationary.

For non-stationary time series two models are generally used:

- The stochastic model with a drift $x(t)= \acute{\alpha} + \rho{*}x(t-1) + \acute{\varepsilon}(t)$,
- The stochastic model with a drift and a deterministic trend $x(t) = \acute{\alpha} + \rho{*}x(t-1) + \beta{*}t+ \acute{\varepsilon}(t)$

where $\acute{\alpha}$, β and ρ are a constant and $\acute{\varepsilon}(t)$ is white noise.

The parameter ρ plays an important role. It can be easily shown (Elder & Kennedy, 2001) that for

- $\rho<1$ a shock in the model gradually disappears;
- $\rho=1$ a shock persists in the system and never dies away;
- $\rho>1$ a shock becomes more influential over time.

Time series with $\rho=1$ are said to have unit roots. Unit roots have profound implications for statistical testing, especially regressions as the conditions required to apply the Law of Large

Numbers and the Central Limit Theorem are violated and, as a result, commonly used test statistics such as t-statistics can no longer be used or lead to spurious results.

If a time series has unit roots, successive differences, d, can transform the series in a stationary one. This series is called to be integrated of order d, or I(d). In most cases the order of integration is 0 (non-integrated stationary series), 1 or 2.

To check for the presence of unit roots a series of tests were developed and the most frequently used are the Augmented Dickey Fuller (ADF test) and the Phillips-Perron (PP) test using as null hypothesis the presence of a unit root (Neusser, 2016). Davidson and MacKinnon (2004) report that the PP test performs worse in finite samples than the ADF test. In this study the ADF test is used. A detailed discussion of these tests and other unit root tests is beyond the scope of this paper and can be found in the literature (Neusser, 2016; Kwiatkowski et al., 1992).

Structural breaks in time series and the Chow test

In a time series an unexpected shift can occur. For example countries' GDP had a shift due to the effects of 1973 oil price crisis. Such a structural break or structural change can lead to errors and unreliability of the model in general (Ho & Iyke, 2017).

Limiting to linear models there are several forms:

- A single break in mean with a known breakpoint;
- A known number of breaks in mean with unknown break points;
- An unknown number of breaks in mean with unknown break points;
- Breaks in variance.

A structural change in time series can influence the results of tests for unit roots (Perron, 1989). Methods have been developed for unit root testing in the present of structural breaks. A distinction can be made between an exogenous, a priori fixed break date and endogenous break dates (Vogelsang and Perron, 1998). As remarked by Perron (2017) the interplay between structural change and unit roots remains an important research topic with a number of open questions.

Visual inspection may suggest a structural break in the time series. To test this assumption the Chow test (Chow, 1960) is often used. The Chow statistics tests whether the single regression line or the two separate regression lines fit the data best with as null hypothesis H0 no structural break in the time series. The Chow statistics is distributed F(k, n1+n2-2*k) where k is the number of estimated parameters and n1 and n2 the number of observations in the two groups. If the Chow statistics is larger than the F-critical value H0 is rejected. The assumption to carry out the Chow test is that the errors in the regressions are serially uncorrelated and homoskedastic.

To test for autocorrelation the Breusch–Godfrey serial correlation LM test (LM test) (Asteriou & Hall, 2016) is used with the null hypothesis H0 of no serial correlation. If the probability p is larger than the critical value H0 cannot be rejected. To remove serial correlation a modified regression model can be used with a one period lag of the dependent variable as an additional independent variable.

The presence of heteroscedasticity, i.e. the variance of the residual in a regression model is not constant, is tested with the Breusch-Pagan-Godfrey (BPG) test or the White test (Asteriou & Hall, 2016). The null hypothesis H0 is homoscedasticity. If the probability p is larger than the critical value H0 cannot be rejected.

Causality

When studying time series one often looks at correlations to test whether and how strongly two series are related. However correlation does not imply causation. Causation indicates that one event is the (partial) result of the other. Granger (1969) developed a methodology to test bi-directional causality between two variables.

The Granger Causality (GC) test uses a bivariate linear autoregressive (VAR) model of two variables x_t and y_t:

$$y_t = \mu_0 + \sum_{i=1}^{k} \alpha_{1i} y_{t-i} + \sum_{i=1}^{k} \beta_{1i} x_{t-i} + \varepsilon_{1t}$$

$$x_t = \varphi_0 + \sum_{i=1}^{k} \gamma_{1i} x_{t-i} + \sum_{i=1}^{k} \delta_{1i} y_{t-i} + \varepsilon_{2t}$$

where

- k is the maximum number of lagged observations included in the model,
- $\mu_0, \alpha_{1i}, \beta_{1i}, \varphi_0, \gamma_{1i}$ *and* δ_{1i} *are* parameters of the model, and
- ε_{1t} and $\varepsilon_{2t}$are residuals (prediction errors) for each time series.

If the variance of ε_{1t} is reduced by the inclusion of the x_t terms in the first equation, then it is said that x_t Granger causes y_t, i.e. if the coefficients β_{1i} jointly significantly different from zero.

This can be tested by performing an F-test of the null hypothesis that β_{1i}= 0 for ∀ i ∈ [1,…, k], assuming the series x_t and y_t are stationary. GC is bidirectional as can be seen from the equation for x_t.

To carry out the GC-test the appropriate model order, i.e. the number of lags k in the regression has first to be determined. There are several approaches and in this paper two of the most frequently used in literature are applied: the Akaike Information Criterion (AIC, (Akaike, 1974)) and the Schwartz Information Criterion (SIC, (Schwartz, 1978)). In case of a difference in the estimated lag length, the AIC is used. In studies with small samples (n< 60) AIC is superior to other information criteria (Mishra, 2014).

The GC-test has a number of limitations. The two variables must be of the same order of integration and to be stationary. To obtain the latter first or higher order of differences of the variables are used in the VAR resulting in the loss of information.

To avoid the problems inherent to the traditional testing of GC, Toda and Yamamoto (1995) developed a procedure by fitting a VAR model in the levels of the variables and adding to the optimal lag length k of the VAR model the highest order of integration dmax of the two variables. A VAR(k+dmax) model is estimated and the coefficients of the last lagged dmax vector are ignored (Zapata & Rambaldi, 1997):

$$y_t = \mu_0 + \left(\sum_{i=1}^{k} \alpha_{1i} y_{t-i} + \sum_{i=k+1}^{d_{\max}} \alpha_{2i} y_{t-i}\right) + \left(\sum_{i=1}^{k} \beta_{1i} x_{t-i} + \sum_{i=k+1}^{d_{\max}} \beta_{2i} x_{t-i}\right) + \varepsilon_{1t}$$

$$x_t = \varphi_0 + \left(\sum_{i=1}^{k} \gamma_{1i} x_{t-i} + \sum_{i=k+1}^{d_{\max}} \gamma_{2i} x_{t-i}\right) + \left(\sum_{i=1}^{k} \delta_{1i} y_{t-i} + \sum_{i=k+1}^{d_{\max}} \delta_{2i} y_{t-i}\right) + \varepsilon_{2t}$$

where

- k is the maximum number of lagged observations included in the model,
- dmax is the maximum order of integration of the two variables in the model,
- $\mu_0, \alpha_{1i}, \alpha_{2i,} \beta_{1i}, \beta_{2i}, \varphi_0, \gamma_{1i}, \gamma_{2i}, \delta_{1i}$ *and* δ_{2i} *are* parameters of the model, and
- ε_{1t} and $\varepsilon_{2t}$are residuals (prediction errors) for each time series.

The null hypothesis of non-causality of x_t to y_t can be expressed as $H0 : \beta_{1i}$ = 0, i ∈ [1,…, k].

To test for GC Toda and Yamamoto developed the Modified Wald (MWald) statistics. The MWald statistics follows a Chi-square distribution asymptotically and the degrees of freedom are equal to the number of time lags (k+dmax).

To carry out the T-Y procedure to test for GC between two time series the following steps are needed:

1. Test each of the time series to determine their order of integration.
2. Let the maximum order of integration of the two of time-series be dmax. For example if one series is I(1) and the other I(2), dmax=2.
3. Make a VAR model in the levels of the data, regardless of the orders of integration of the time series.
4. Determine the appropriate maximum lag length for the variables in the VAR, k, using the appropriate tests such as AIC and SIC.
5. Test that the VAR model is well-specified. For example, test that for the residuals the serial correlation, the normality and the homoskedasticity. As already explained to test for the presence of serial correlation the LM test is used and for homoskedasticity the White test. The Jarque-Bera test (Jarque & Bera, 1980) tests for normality by measuring the difference of the skewness and kurtosis of the series with those from the normal distribution with the null hypothesis of a normal distribution. If necessary, the value of k can be increased until the autocorrelation issue are resolved.
6. In the VAR model to the lag length k dmax additional lags of the two variables are added into the two equations.
7. Test for Granger causality where the dmax lags that are added, are not included when carrying out the Wald test for they were added to assure that the Wald statistics is asymptotically chi-square distributed.
8. Rejection of null hypothesis supports the presence of GC.

Empirical results

Structural break in the publication output

Figure 1 shows the evolution between 1999 and 2017 of the number of publications, using full and fractional counting (further full- and fractional-counted publications). The overall impression is a fairly linear increase during the first part of the 19 year period followed by a linear increase with a shallower slope or even a decrease. This evolution is more pronounced for the fractional-counted publications. For Denmark (full counting scheme), the publication output shows the opposite behaviour, with a stronger increase over the last part of the period.

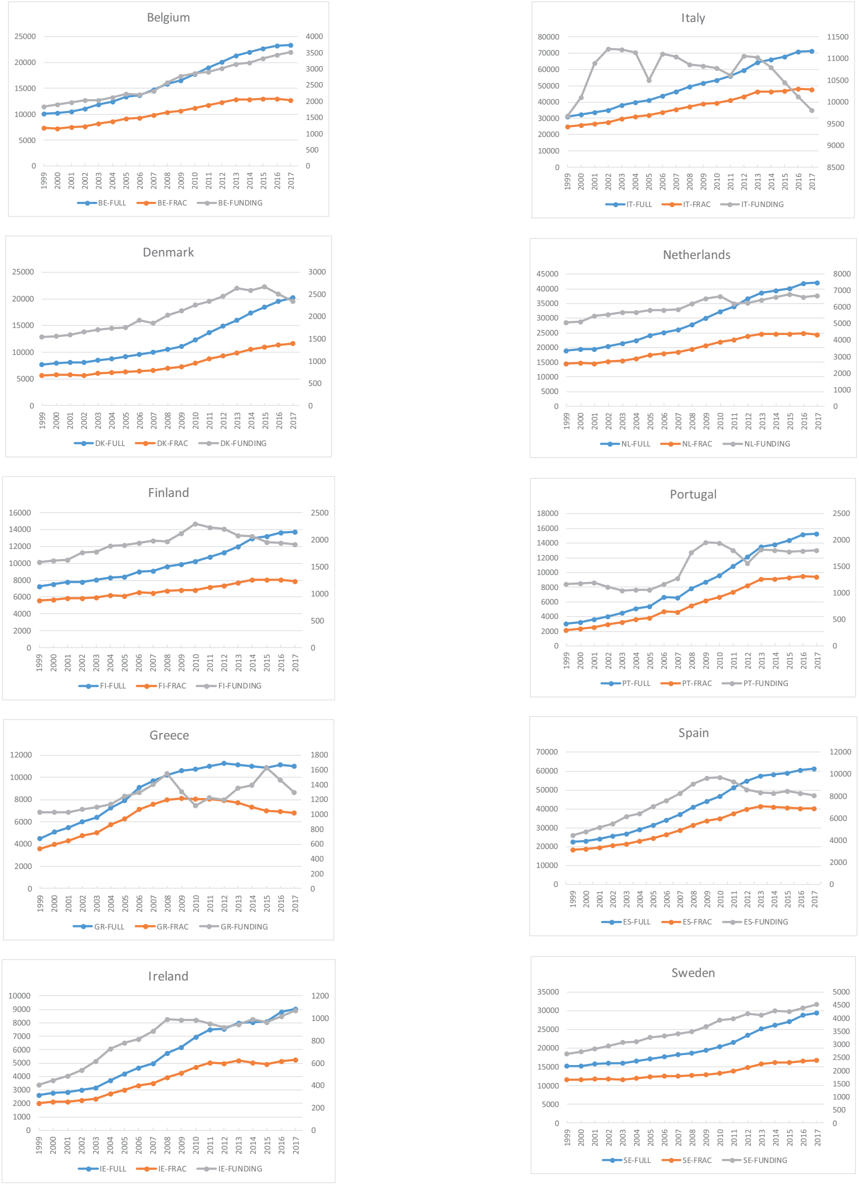

Figure 1- For each country in the panel the evolution of the number of publications, full counting scheme (XX-FULL) and fractional counting scheme (XX-FRAC) on the left Y-axis and the funding (XX-FUNDING), (HERD + GOVERD) at constant prices and PPP $ in $ million 2010 on the right Y-axis. The period is 1999-2017.

Table 1 – For evolution of the number of publications, full (Full) and fractional (Frac) counting scheme, the Chow statistics (Chow stat) is given for the breakpoint year (Breakpoint). At 5% significance level the critical value is F(3,13)= 3.41. The null hypothesis 'no break at the specified breakpoint' has to be rejected for values of the Chow statistic larger than 3.41. The residuals of the regression are tested for serial correlation (p LM-test) and homoscedasticity (p BPG test); for both tests the null hypothesis (no serial regression; homoscedasticity) has to be rejected for p-values smaller than the 5% significance level. The time period is 1999-2017.

The Chow statistics is used to test whether there is a structural break in the countries' publication output. Chow test uses an exogenous break date. Table 1 confirms the observations from the visual inspection of the graphs. For Portugal the null hypothesis of no structural break cannot be rejected for the full counting scheme. A sensitivity test was done by calculating the Chow statistic for years around the selected break year resulting in no substantial changes in the Chow statistics.

For all countries in the sample a break is observed in 2010-2012 except Finland (fractional counting scheme, 2013), Greece (fractional counting scheme, 2009), and Italy (full counting scheme, 2013). In the interpretation of the Chow statistics some caution is needed for Spain and the Netherlands, and in the fractional counting scheme for Greece and Ireland as serial correlation in the residuals is observed.

The observed decrease in publications is not due to changes in the coverage of the WoS. In the period 1999-2017 the number of publications processed for the WoS increases by 1 million with some fluctuations over the years due to changes in the coverage of the database.

Visual inspection of the plots (Fig. 1) learns that in the same period the research expenditures decreased except for Belgium and Sweden. For these two countries the research expenditures increased over whole period 1999-2017 and no break is observed. For Ireland, Finland, Netherlands, Portugal, and Spain there is a break in the funding data around 2008-2009 and for Denmark around 2013. Italy's research expenditures data are rather flat with no pronounced trend till 2012 when the stagnation changed in a decrease. For Greece the research expenditures increase till 2008 to become in the following years rather erratic.

Todo-Yamamoto approach to Granger causality between research expenditure and publication output

To carry out a statistically meaning full GC-test the sample size must be at least 30 (Mackinnon, 1996) For most countries in the sample in the 80's of last century a break in the publication output can be observed with 1987-1988 as break date. To avoid the influence of this break on the results the time series were limited to a 30 year period: 1988-2017. In this paper only the results of GC-test between the research expenditures and the full-counted publications are presented.

To study the order of integration of the research expenditures and the full-counted publications two approaches are used:

- The standard unit root test with the ADF test with drift and trend options;
- The breakpoint unit root test with the ADF test with for the basic trend specification and for the breaking trend specification drift and trend options.

The reason for this approach is the presence of structural breaks which can lead to size distortion in standard ADF test (Ho & Iyke, 2017).

The tests were done with the EViews application for unit root testing. A detailed description of the tests can be found in the EViews 10 User's Guide II (EViews 10, 2017a)

All series are level stationary or first difference stationary except for Belgium's full-counted publication series that is stationary at second difference. As for each country in the sample at least one series is I(1), the parameter dmax is 1 for the TY approach for GC, except for Belgium with dmax=2.

Table 2 gives the optimal lag length k for the VAR model with the full-counted publications and the research expenditures. The LM-test, the Jarque-Bara test and the White test were done. No serial correlation or heteroscedasticity are found in the residuals which are normally distributed, except for Portugal. For this country the p-value of the Jarque-Bara test is smaller than the critical value resulting in the rejection of the null hypothesis of normality.

For each country with the optimal lag length k and the maximum order of integration of the 2 variables dmax a VAR (k+dmax) model was estimated with the additional lag(s) as exogenous variable. The bidirectional GC-test was performed with the null hypothesis that research expenditure does not Granger cause the full-counted publication output or alternatively that the full-counted publications output does not Granger cause research expenditures. Table 2 gives the MWald statistics and the p-values.

The results suggest that at the 5% significance level a unidirectional causality runs from funding to publications for Belgium, Spain, Greece and Ireland. Only for Ireland a bidirectional causality between the two variables can be observed. For Denmark, Finland, Italy, Netherlands, Portugal and Sweden the null hypothesis of no GC in both directions cannot be rejected.

At the 10% significance level for Denmark and Portugal the null hypothesis that research expenditure does not Granger cause full-counted publications can be rejected.

Table 2 – The reslts of the T-Y approach for GC for the countries (CO) in the panel: hypothesis (H0), lag length (k), maximum order of integration of the 2 series (dmax), modified Wald statistics (MWald), p-value and Decision using 5% significance level.

Concluding remarks

For all countries in the panel except Sweden, the growth rate of the full-counted publication output was lower in the last 4-5 years of the period 1999-2017 compared to the years before.

As already mentioned in subsection ‘Structural break in the publication output’, these trends cannot be explained by changes in the coverage of the WoS. One of the possible causes may be the reduction in public research funding. However, there are exceptions. Although the public funding for higher education and public research institutes increased steadily between 1999 and 2017, for Belgium and to some extent Sweden the growth rate of the full-counted publications was lower in the last quarter of the period compared to the earlier years.

For the fractional-counted publication output the reduction in the growth rate was more pronounced compared to the full-counted number of publications and for some countries this growth rate was flat or even negative in the last quarter of the period. The difference in growth rates between the two counting schemes can be explained by an acceleration in the international collaboration. However, it is remarkable that this acceleration happened 3 to 5 years after funding reductions started to be implemented in 7 out of 10 countries in the panel. Moreover around the same year it is also observed in the two countries where research expenditures grew at a nearly steady rate over the entire period.

Part of the time lag between the changes in the funding and the publication output could be explained by the research cycle: obtaining a grant, carrying out the research work, submitting a manuscript and lastly its publication in a peer reviewed journal. Although there are differences between disciplines the publication process takes about a year (Bjork & Salomon, 2013) and in most countries the majority of research grants cover 2 to 4 years.

Further work is necessary to test this hypothesis taking into account the model's limitations. Governments are not the only funding source for research at higher education and public research institutes and their output is not limited to publications in journals covered by the WoS.

One approach to explore the causal relationship between funding and publication output is presented in the second part of this paper. The results can be summarized as follows: for the period under study at the 10% confidence level for 6 out of the 10 countries the Toda-Yamamoto approach for Granger causality shows a unidirectional causality between funding and publication output. At the same confidence level this relationship is even bidirectional for Ireland.

This results suggest that at a country level changes in public research funding affects with a certain delay the nation's publication output. But also more counter-intuitively that changes in publication output have an effect on public research funding. In some national performance-based research funding systems a university's publication output is linked to its further public funding (Hicks, 2012). In some countries to manage at arm's length public research institutes governments use key performance indicators linked to the allocation of funding. It remains an open question to what extent, if implemented, these incentive based schemes have at the national level an impact on the volume of public research funding.

The interpretation of the results of the analysis must however be done carefully. Besides the reduction of a complex world to a model with 2 proxy indicators and the problems related to the use of OECD funding data (Aksnes et al., 2017), the Granger causality test has its own methodological limitations such as its sensitivity on the selection of the optimal lag in the VAR model and the low number of available data points in the time series. Further work is necessary not at least to include multiple breakpoints to be able to use longer time series and more variables such as granted patents as a variable. Notwithstanding the necessary caution, for time series analysis powerful analytical tools have been developed and they are applied in many disciplines. To the best of our knowledge they have not yet been used to study bibliometric data.

Abstract

The bibliographic database Web of Science (WoS) provides information about the top scientific actors through its Essential Science Indicators (ESI) product. One of the most important reports is the highly cited papers (HCP), that shows the Top 1% of papers cited in the 22 research field and publication year. New metrics based on online attention, the Altmetrics, have appeared. Using these metrics as a reference, our primary aim in this work is to offer an overview of the social media attention of the HCP. To do so, a match between the 148,767 WoS documents and their Altmetrics scores was performed using their DOIs in Altmetric.com (94,147 records). Then, a descriptive and correlation analysis were performed to describe the results. This analysis shows that Twitter is the leading social platform in which the HCP are disseminated and a source for News. Facebook is the third one, but probably it is not preferable for scientists. Our analysis also indicates that there are research fields with higher social attention and are those with a scientific output more transferable to society. The linkage between basic research and societal impact (patent and policy documents) seems to be low.

Introduction

It is well-known that the Web of Science (WoS) bibliographic database is for most researchers and institutions the primary source of information and the basis for academic career evaluation. The current provider, Clarivate Analytics, offers to the scientific community the InCites Essential Science Indicators (ESI). It is an analytic tool for identifying the top scientific actors through the WoS-indexed items, evaluating the impact of countries, institutes and scientists (Hu, Tian, Xu, Zhang, & Wang, 2018). Furthermore, a fundamental component of ESI is the Highly Cited Papers (HCP), which provides information about the most cited articles in each of the 22 research fields. In other words, it represents the Top 1% of papers cited in their field and publication year (Bauer, Leydesdorff, & Bornmann, 2016).

Nonetheless, although this tool provides relevant information about the influence of the research at different levels, it has its detractors, due to the procedure employed to identify the Top 1% HCP (Hu, Tian, Xu, Wang, et al., 2018; Hu, Tian, Xu, Zhang, et al., 2018; Miranda & Garcia-Carpintero, 2018). In that way, ESI does not consider the influence of the month of publication on the citation counts and establishes the citation window when it is published (without taking into account the online-first option). Moreover, they only use 22 research fields for more than 11,000 journals and is limited to the journal level. According to previous research (Ruiz-Castillo & Waltman, 2015), an article-level classification with 5119 research fields seems to be more suitable to identify the HCP. Finally, ESI takes into account two types of publications, reviews and articles, and it is known that reviews obtain three times more cites than articles (Glänzel, 2008). Despite this, it is interesting to analyse the characteristics of this set of documents, since they attract the attention of the scientific community (Bornmann, Bauer, & Schlagberger, 2018; Docampo & Cram, 2019; Kolditz, Dörhöfer, LaMoreaux, & Kolditz, 2018; Li, 2018; Zhang, Wan, Wang, Zhang, & Wu, 2018).

Although the classic bibliographic databases, such as WoS, are still an important source of information, several changes in the scientific output dissemination are happening. The agreement about the necessity of new forms of evaluating the research impact is clear (Mohammadi, Thelwall, Haustein, & Larivière, 2015). With social media, new actors have emerged (e.g. practitioners, undergraduate students, or lecturers with teaching or professional purposes), and even there are non-authors professionals, which read and perform critical analysis of research articles, and now also share them. Furthermore, new types of academic outputs have been appeared, such as datasets, posters, blogs, or online teaching. Thus, it is now accepted that the research output is not only disseminated within the scientific community as traditionally has been (Bornmann & Williams, 2013). In this sense, the appearance of social media is now highly present in academia, promoting new ways for measuring the impact or attention of the scientific production (Costas, Zahedi, & Wouters, 2015). These types of metrics are known as Altmetrics (Priem et al., 2011), and they are focused on the analysis of the article impact based on the social web. Currently, they do not substitute the traditional metrics (generally, citations), but they could be considered as complementary.

Although a book chapter about the differences between the Top 100 articles according to WoS and Altmetrics was published in 2016 (Banshal, Basu, Singh, & Muhuri, 2018), to our knowledge, no documents are providing an analysis of the whole set of HCP. Therefore, our primary aim is to show an overview of the social media attention of the HCP based on the Altmetrics. Three different subgoals were established to obtain the proposed overview: 1) to show the descriptive data of the social attention in all the platforms measured by Altmetric.com, 2) to analyse the existing correlation among the main social, policy, patent and news platforms, 3) to show the social, policy, patent and news social media attention for each research field, in number of mentions and percentage. To do this, this paper is organized as follows: i) Methods section, in which the procedures employed to obtain and analyse the information are described, ii) Results section, in which the results are detailed, showing the different aspects about the social media attention of the HCP, and finally, iii) Discussion and conclusions section, where the main implications of the study are stated.

Methods

In order to analyse the social media attention of the HCP, several tasks to obtain the data and process it were performed.

Dataset

The set of documents to carry out the analysis was obtained from the WoS list of HCP. In that way, it is important to take into account that historically it has been stated that WoS indexes the most important research output related to the different scientific disciplines since they are considered as a primary criterion in tenure, promotion and other professional decisions (Hodge & Lacasse, 2011; Seipel, 2003). Nevertheless, it has also been stated that this database does not cover some specialities adequately, such as social sciences and humanities (Mongeon & Paul-Hus, 2016).

To perform the proposed study, the list of the DOIs of the documents published by the HCP was obtained from WoS in December 2018. As shown in Table 1, a total of 148,767 documents were retrieved (1,338 documents did not have DOI). Then, they were matched with the data available in Altmetric.com. It is a commercial tool that monitor, analyses and records the online activity around research outputs from a set of online sources, such as blogs, Twitter, Facebook, Google+, news, media, and other sources (Adie & Roe, 2013; Costas et al., 2015). A total of 94,147 records were finally analysed, corresponding to the period 2008-2018. It is important to highlight that only 64% of the documents from WoS matched with Altmetric.com data.

Altmetrics analysis

In order to show the social media attention of the HCP and the correlation between the main social, policy, patent and news mentions, different analyses were carried out. First, the descriptive analysis of all the platforms measured by Almetric.com was performed for the whole set of documents; furthermore, statistical analysis based on correlations was employed to show the relationships among the main social, policy, patent and news mentions. Then, the number of mentions of each research field and the percentage of these mentions and WoS citations were analysed.

In that way, the correlation analysis applied to the whole period could be problematic. First of all, the Altmetric.com started to record the Altmetrics data in 2011 systematically, so we cannot consider the previous years (Robinson-Garcia, Arroyo-Machado, & Torres-Salinas, 2019). Furthermore, the Almetrics data corresponds to December 2018, so the very recent documents tend to have a fewer number of citations and mentions (Thelwall & Nevill, 2018). In order to solve this situation, the period 2012-2015 was selected to obtain a mature dataset (4-7 years old).

The statistical analysis was performed using the software IBM SPSS 25 (Armonk, New York, USA). First, the Kolmogorov-Smirnov test for all the variable mentions was $p<0.001$. Thus, they do not follow a normal distribution. Then, the Spearman correlation test was employed to analyse the correlation between the different variables.

Results

In this section, the characteristics of the 117,674 documents analysed are shown. First, in Table 2 the descriptive analysis of the mentions measured by the Altmetric.com is shown. These results are ranked by the number of mentions, being Twitter clearly the platform with the highest number of mentions (74.74%), followed by News (9.67%), Facebook (4.77%) and Patents (3.53%). In that way, the social platforms with the lowest number of mentions were Syllabi and LinkedIn.

Hereafter, the correlation study results of the main platforms are shown in Table 3. In this sense, the Policy mentions, although they are not in the Top 5 platforms concerning the number of mentions, were selected due to the relevance of this kind of documents. Overall, the mentions on Twitter and Facebook platforms are the most correlated, followed by Twitter and News. Conversely, the Policy and Patent mentions are less correlated. Nevertheless, several aspects will be discussed in the Discussion section.

Table 1. The number of documents with and without DOI and Altmetrics indexed in Web of Science database.

Research Field	*Items*	*Items with DOI*	*Items without DOI*	*With Altmetrics*	*%*	*Without Altmetrics*	*%*

Finally, in order to analyse the social media attention of each research field, two different figures are shown. First, Figure 1 presents the mean of mentions of these research fields. As can be seen, the Multidisciplinary field (161.84) has the highest mean attention on Twitter, followed by Molecular Biology & Genetics (68.42) and Clinical Medicine (52.74). Those fields with the lowest mean attention in Twitter are Mathematics (2.73), Materials Science (2.99) and Chemistry (3.72). According to Facebook mentions the highest mean attention is for Multidisciplinary (9.38), Clinical Medicine (3.86) and Molecular Biology & Genetics (3.50). The lowest mean attention is for Mathematics (0.07), Engineering (0.20) and Chemistry (0.26). Considering News mentions, the most relevant are Multidisciplinary (21.34), Geosciences (9.88) and Space Sciences (8.89). The lowest mean attention is for Mathematics (0.04), Engineering (0.59) and Computer Science (0.80). Although in these variables some changes can be observed, the main differences are in Patent and Policy mentions. In the case of Patent mentions, the highest mean attention is for Molecular Biology & Genetics (68.42), Multidisciplinary (3.62) and Biology & Biochemistry (3.30), while the lowest are for Space Science (0.01), Economics & Business (0.02) and Social Sciences (0.05). According to the

Policy mentions, the highest mean attention is for Economics & Business (1.83), Multidisciplinary (1.18) and Social Sciences (1.08). The lowest mean attention is for Space Science (0.02), Physics (0.02) and Chemistry (0.02).

Table 2. Description of mentions in Altmetric.com by platform with at least 1% of total share from all the publications indexed in Web of Science that belong to the highly cited papers.

Table 3. Spearman correlation coefficients of the different selected variables from the period 2012-2015 Altmetric.com data.

Platforms	*Twitter*	*News*	*Facebook*	*Patent*	*Policy*
Twitter	1	0.526	0.591	-0.051	0.206
News	0.526	1	0.482	0.013	0.203
Facebook	0.591	0.482	1	-0.010	0.165
Patent	-0.051	0.013	-0.010	1	-0.094
Policy	0.206	0.203	0.165	-0.094	1

All the correlations were significant.

Finally, in order to analyse the social media attention of each research field, two different figures are shown. First, Figure 1 presents the mean of mentions of these research fields. As can be seen, the Multidisciplinary field (161.84) has the highest mean attention on Twitter, followed by Molecular Biology & Genetics (68.42) and Clinical Medicine (52.74). Those fields with the lowest mean attention in Twitter are Mathematics (2.73), Materials Science (2.99) and Chemistry (3.72). According to Facebook mentions the highest mean attention is for Multidisciplinary (9.38), Clinical Medicine (3.86) and Molecular Biology & Genetics (3.50). The lowest mean attention is for Mathematics (0.07), Engineering (0.20) and Chemistry (0.26). Considering News mentions, the most relevant are Multidisciplinary (21.34), Geosciences (9.88) and Space Sciences (8.89). The lowest mean attention is for Mathematics (0.04), Engineering (0.59) and Computer Science (0.80). Although in these variables some changes can be observed, the main differences are in Patent and Policy mentions. In the case of Patent mentions, the highest mean attention is for Molecular Biology & Genetics (68.42), Multidisciplinary (3.62) and Biology & Biochemistry (3.30), while the lowest are for Space Science (0.01), Economics & Business (0.02) and Social Sciences (0.05). According to the Policy mentions, the highest mean attention is for Economics & Business (1.83), Multidisciplinary (1.18) and Social Sciences (1.08). The lowest mean attention is for Space Science (0.02), Physics (0.02) and Chemistry (0.02).

Second, Figure 2 shows the percentage of mentions and WoS citations in the different research field. In this sense, the mean of mentions and standard deviations for each social platform is more or less similar (Twitter (3.62± 4.52%), Facebook (4.00± 4.34%), News (3.83± 4.53%) and Patent (3.60± 4.06%)), except to Policy (2.14± 5.03%) that is lower and its standard deviation higher; conversely, the WoS mean citations (4.25± 1.86%) for all the research fields are higher than in social mentions, but with a lower standard deviation. Also, the documents published in the Multidisciplinary field attract the highest attention in the selected platforms, but that does not occur in WoS, where the highest cited field is Molecular Biology & Genetics. In order to better understand these differences between social platforms and WoS, Table 4 shows the mean percentages for the 22 research fields.

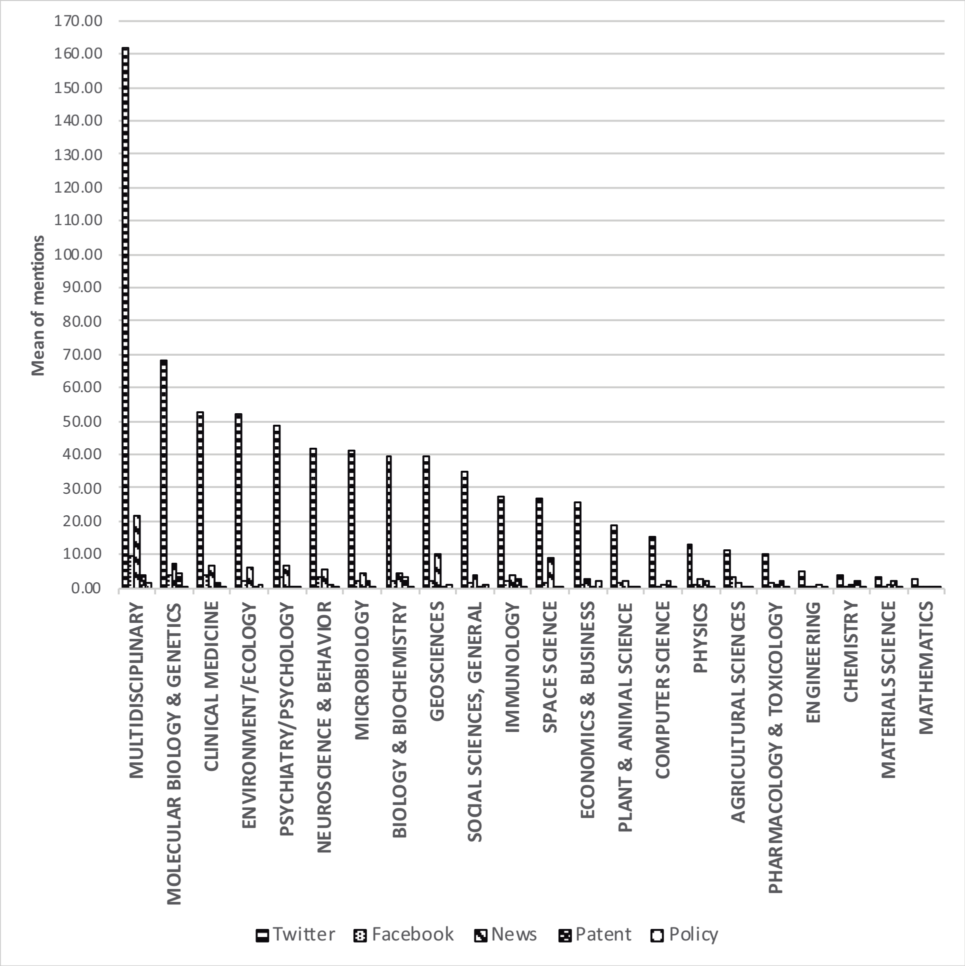

Figure 1. Mean of mentions of the different research field in Twitter, Facebook, News, Patent and Policy documents.

Discussion and conclusions

Once the analysis has been performed, an overview of the social attention of the HCP is discussed. In general, several differences among the research fields were detected. While the mean of citations in WoS seems to be more or less uniform in all the research areas, the social attention unequally focused. Nonetheless, we consider that the results need to be taken with caution. As stated in the Methods section, the percentage of documents without Altmetrics is relatively high (36%); nevertheless, this situation is frequent in this type of analysis (Bornmann & Haunschild, 2018; Didegah, Bowman, & Holmberg, 2018; Moral-Munoz & Cobo, 2018). This data is important in an overall perspective, but it is even more relevant if it is taken into account in each field. Mathematics, Computer Science and Engineering have more than 70% of documents without Altmetrics information. Thus, these documents could be attracting the attention of social media, but they were not measured or the dissemination was performed by different means.

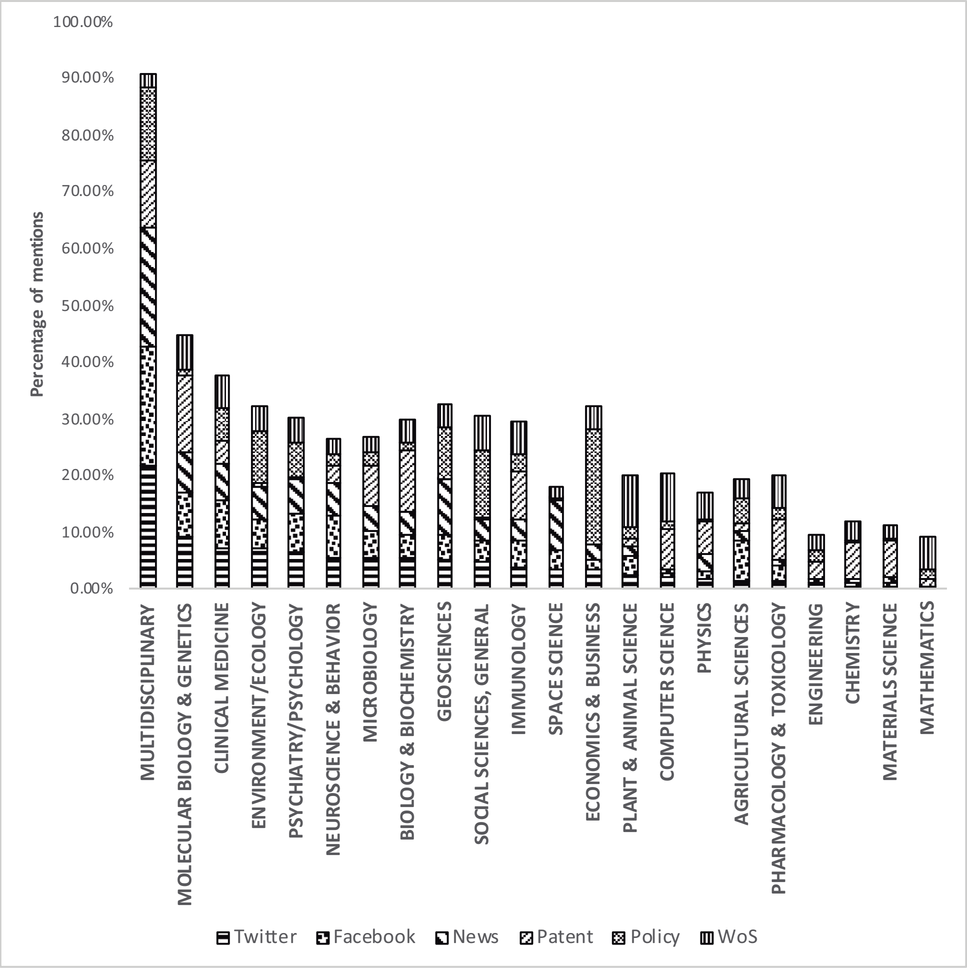

Figure 2. Percentage of mentions and WoS citations of the research fields.

When the total amount of social mentions is considered, Twitter is the platform which the most scientific production is disseminated; followed by the News. In this way, it is well-known the special status of Twitter in the dissemination of relevant news (Banshal et al., 2018; Orellana-Rodriguez & Keane, 2018). Similarly, it has become the place where research consumers (academics, students, clinicians, etc.) converge to report, read, discuss and share new findings. Furthermore, journalists are using this platform to identify potentially highly social relevant news. Thus, it is accepted that Twitter is a way for the scientists to reach a wide popular audience, although it requires a high online engagement and having approximately 2,200 followers at least (Côté & Darling, 2018). Facebook, considered as the most popular social network worldwide with 2,271 millions of users in January 2017 (Statista, 2019), is the third social platform in which the HCP were mentioned. Probably, this is reflecting that scientists are not on Facebook; they prefer to use Twitter as a communication mean. Nonetheless, it is important to highlight that the majority of the Twitter followers of scientists are other scientists (Côté & Darling, 2018). On the contrary, LinkedIn, that is another important social media, has a very low number of mentions. This finding is not in line with previous results (Mas-Bleda, Thelwall, Kousha, & Aguillo, 2014), where it was stated that LinkedIn was the most popular social web for highly cited researches. Consequently, the presence of highly cited researchers on LinkedIn is high, but they do not share their output on this platform.

Table 4. Mean percentages of WoS citations vs. social media attention.

Research Field	*WoS*	*Soc.*
Agricultural Sciences	2.31%	1.49%
Biology & Biochemistry	6.07%	4.18%
Chemistry	6.02%	0.58%
Clinical Medicine	4.37%	6.50%
Computer Science	4.27%	1.54%
Economics & Business	2.73%	2.63%
Engineering	2.73%	0.69%
Environment/Ecology	4.16%	5.94%
Geosciences	3.87%	5.29%
Immunology	6.21%	3.75%
Materials Science	5.63%	0.62%
Mathematics	2.09%	0.37%
Microbiology	4.24%	4.63%
Molecular Biology & Genetics	9.25%	7.75%
Multidisciplinary	8.17%	20.77%
Neuroscience & Behavior	4.95%	5.60%
Pharmacology & Toxicology	3.44%	2.20%
Physics	5.55%	1.77%
Plant & Animal Science	2.59%	1.98%
Psychiatry/Psychology	3.43%	6.40%
Social Sciences, General	2.23%	3.90%
Space Science	5.68%	3.41%

According to the correlation analysis, it was found that only Twitter and Facebook are more correlated; presumably, due to their social nature and the use by a wider group of the population. News are correlated with Twitter and Facebook, such as stated above, journalists are using social platforms as a place where discuss and identify relevant news (Orellana-Rodriguez & Keane, 2018), so this finding is in line with these previous results. In addition, Patent and Policy documents are low correlated to the rest of the platforms. This reflects the question about the linkage between basic research literature and the societal impact, assuming that this impact exists *"when auditable or recorded influence is achieved upon non-academic organization(s) or actor(s) in a sector outside the university sector itself—for instance, by being used by one or more business corporations, government bodies, civil society organizations, media or specialist/professional media organizations or in public debate. As is the case with academic impacts, societal impacts need to be demonstrated rather than assumed. Evidence of external impacts can take the form of references to, citations of or discussion of a person, their work or* *research results"* (Wilsdon et al., 2015). In that way, our findings show a low linkage between the academic and social, though the information provided by Altmetrics has to be taking into account with caution (Bornmann, Haunschild, & Marx, 2016).

Finally, some results about the research field analysis need to be discussed. The first and most important finding is the high social impact of the Multidisciplinary field; with only 207 documents it reaches the highest number of mentions in almost all the platform measured. This is not as surprising when we discover that these documents are published in Nature and Science journals. Thus, the high impact of the documents published in these journals is undisputed. Furthermore, in an overall perspective, the fields attracting the social attentions are those with an output more transferable to the social application, such as Molecular Biology & Genetics, Clinical Medicine or Psychiatry/Psychology. On the other hand, those with the lower application were less mentioned, such as Mathematics, Materials Science and Chemistry. Nonetheless, this does not correspond to the WoS citation relative attention, since the mean percentage for each field is more similar than the social one. Thus this is related to the assumption previously stated in the literature, *"the journals that draw public attention are not the ones that are highly cited except for a small number that receives attention from both the public and academics"* (Banshal et al., 2018).

Although the findings shown in the present work are interesting and present a new overview of the social attention of the HCP, some limitations should be stated. First, due to the characteristics of the Altmetrics, only a percentage of the publications indexed in WoS was analysed; in some research fields, the percentage of documents without Altmetrics is very high. Thus, the results and conclusions of the present study are influenced by the set of documents obtained, due to the methodology drawbacks influential papers could not be included. Second, only a few social platforms were analysed to avoid a text too long and difficult to understand. Third, it should be realised that the output of the different platform needs to be considered in their context. Each platform was designed with a purpose; for example, tweets are designed to be short and very numerous, with an easy way to share. Finally, the intentional mentions by the publisher, the editor of the journal, the author or bots were not analysed. As future research, a study contrasting the HCP with the non-HCP will be performed. This new analysis will discover if there is a different behaviour in social share when a paper is designed as HCP.

The present study shows several findings of the social attention of the HCP. Broadly speaking, the academic, patent and policy attention is not in line with the social attention. Twitter is the main social platform for which the HCP information is disseminated and is related to the share on News. Also, the documents published in journals of a field with a more transferable application to the society obtain higher social attention. Although these are the primary findings of this broad overview, further analysis dividing the documents by periods and deepening in their characteristics is still needed.

Industry involvement in biomedical research: authorship, research funding and conflicts of interest

Belén Álvarez-Bornstein[1] and María Bordons[1]

Abstract

Industry plays an important role in biomedical research, especially in clinical and translational research. From a bibliometric perspective, its contribution to research may take different forms, which range from authorship to research funding. Moreover, relationships with industry are increasingly mentioned by authors as potential conflicts of interest (COI), which are very often included in papers under the funding acknowledgment section. This study analyses the contribution of industry in its dual facet of authorship and funder to the scientific publications of Spain-based authors in a biomedical field in Web of Science (WoS) during 2010-2014. Funding acknowledgment data are examined to determine the presence of industry funding and to assess the accuracy of WoS in extracting firms reported as funders, discriminating between funders and entities mentioned due to COI. Frequency of COI disclosure and its main types are described. The influence of a number of variables on the likelihood of papers to present COI is studied. Results show that WoS is not always able to discriminate between funders and companies mentioned due to COI. Industry appears less often as an affiliation of authors than as a source of research funding in this study, but the latter can be overestimated due to the confounding effect of COI.

Introduction

Industry plays an important role in biomedical research. It accounts for almost two thirds of R&D funding in developed countries (OECD, 2015), contributes to major advances in basic and, in particular, in clinical and translational research, and is responsible for a notable share of scientific publications in the biomedical domain.

The involvement of industry in research takes many forms and entails different levels of engagement which ranges from financial support to active participation in the research. Accordingly, from a bibliometric perspective, studying both industry funding and industry authorship can be useful to obtain a more comprehensive view of its contribution to research (Lundberg, Tomson, Lundkvist, Skar & Brommels, 2006).

Approaching the study of industry as a funding source is enhanced at present by the coverage of funding acknowledgments in different databases such as Web of Science or Scopus. Moreover, the fact that the inclusion of funding acknowledgments in publications is becoming mandatory in science increases the interest of this type of study and the significance of the results. However, the analysis of funding data is hampered by their collection in a non-structured section with heterogeneous content comprising financial support but also technical or intellectual assistance as well as conflicts of interest (Álvarez-Bornstein, Morillo & Bordons, 2017). This may lead to errors in the collection or interpretation of funding data, such as confounding funders and companies mentioned due to conflicts of interests in publications, which may distort the results of the studies (Lewison & Sullivan, 2015).

This problem might get worse over the years, as the need to declare potential conflicts of interest (COI), that is, the relationships of authors with entities which might be affected by the research, is increasingly advocated. This is particularly relevant when industry is involved in the research because of its economic interests that may have a negative influence on the objectivity of science and may foster bias in study conclusions. In fact, financial ties of pharmaceutical industry to researchers have been associated with an increased likelihood of reporting results favorable to the intervention being studied (Tungaraza & Poole, 2007; van

Lent, Overbeke & Out, 2013). Disclosure of conflict of interest is thus requested to avoid potential bias and allow readers to form their own opinion about the value of a study.

Previous studies have explored the presence of COI statements in publications in different specialties (e.g.Hakoum et al, 2017), but as far as we know the potential confounding effect of COI on funding data collection has only been analysed in the study of Lewison and Sullivan, who found a decrease in around 40% in the share of papers funded by industry in respiratory diseases after COI removal. Extending the study to other disciplines and including a more detailed analysis of sources of error is needed. Although many professional organisations have developed recommendations about different type of conflict of interest which need to be disclosed (e.g. ICMJE), the lack of a well-established taxonomy hinders this type of study.

In this context, different questions are addressed in this paper. Firstly, we analyse the presence of industry funding and COI in a set of biomedical publications to study whether WoS is able to discriminate correctly among firms mentioned as research funders and those included in a COI statement. Secondly, frequency of COI disclosure and its main types are described while driving factors of COI are explored. Finally, we examine what role (authorship/funding) is played by industry in scientific publications and to what extent funding involvement can be overestimated due to incorrect inclusion of COI.

Methods

Scientific articles by authors based in Spain and published during 2010–2014 were selected from WoS in Cardiac and Cardiovascular Systems (CARD), which is a clinically-oriented domain. The delimitation of this domain was based on the WoS classification of journals into subject categories. Only citable items (articles and reviews) published in English were considered, since FAs are regularly covered by WoS only for items published in this language (Alvarez-Bornstein et al., 2017). A total of 2752 publications were included in the analysis.

Organizations included in the address of authors were normalized and automatically classified into different institutional sectors and papers with an industry affiliation were identified. Concerning funding acknowledgments, they are structured in WoS in three sections: the full text of acknowledgments as it appears in publications (FX), “funding agency” (FA) and “grant number” (GN). In this study, the funding agencies included in the FA section of CARD papers were normalised according to a master file of agencies built at our institution. This master file includes for each agency, its full-normalised name, acronym (if any), institutional sector, type of funding (public, private, mixed) and country.

The full text included in the FX section of publications was manually examined to identify COI and funding agencies and compare them with those included by WoS in the FA section. It was sometimes difficult to determine whether a given funding agency was reported by authors as supporter of the current research or due to previous ties that may lead to COI. To discriminate between both, the guidelines proposed by Lewison & Sullivan (2015) were followed. Detected COI were grouped into seven categories, which include: personal fees, research-support, employment, non-monetary support, patents, stock ownership and drug or equipment supplies. This classification was taken from the literature (Hakoum et al, 2016), after minor adjustments. Multivariable regression analysis was used to assess the predictors of COI presence, that is, the influence of different variables on the likelihood to disclose COI. Main dependent variables included: type of funding (only, public, only private, both), number of funders (1 funder, 2-4, more than 4), foreign funding (0=No, 1=Yes), international collaboration (0=No, 1=Yes), first quartile journal (0=No, 1=Yes) and research level (1=basic, 2=clinical). As a proxy for the basic or clinical nature of the research, we have used the research levels described by Boyack et al (2014), derived from the CHI classification of journals into research levels. It ranges from 1 –most applied– to 4 –most basic–, but they were aggregated into two broad classes: clinical and basic.The statistical package SPSS was used (v.22). It should be noted that the analysis of COI is limited to funded publications, since acknowledgments are collected by WoS only if they include funding information. Finally, the participation of industry as affiliation of authors and as funding source of research was analysed.

Results

A total of 2752 papers in CARD were published by scientists based in Spain during the period 2010-2014. Funding acknowledgments were available in 57% of CARD papers (n=1572) and the government was the main funding source since it was present in 2/3 of the funded publications. Regarding industry, it was acknowledged in almost half of the funded papers (table 1).

Table 1. Distribution of CARD funded papers by type of funding source (FA data)

	No. Papers	*%*
Government	1026	65.27
Industry	710	45.16
NPO	486	30.92
Higher Education	208	13.23
Unknown sector	6	0.38
Total	1572	

NPO= Non-profit organization

The funding text (FX) of papers was manually examined to identify the presence of COI and assess to what extent some of the organizations mentioned due to COI could have been erroneously considered funders and extracted to the FA section by WoS. A total of 710 papers were funded by industry according to agencies collected by WoS in the FA section (table 1), while this figure falls to 570 after our manual revision of data (table 2). In 149 papers (21%) some companies mentioned due to potential conflict of interest were erroneously recorded by WoS as supporters of the current research (false positive data), while no industry funding was recorded in the FA section of 9 papers which acknowledged it in the full text (1%) (false negative data). Accordingly, the share of industry funded papers in CARD declined from 45% to 36% after manual revision of data.

Table 2. Identification of industry funded papers in CARD by type of analysis

	By analysis of FA		
By manual revision of FX	*No industry*	*Industry*	*Total*
No industry	847 (98.90%)	149 (21.00%)	996 (63.60%)
Industry	9 (1.10%)	561 (79.00%)	570 (36.40%)
Total	856 (100%)	710 (100%)	1566* (100%)

*6 papers with unknown institutional sector of funding are not considered

Considering all funded CARD papers, an explicit statement about the presence or absence of COI in the manuscripts was observed in 27% of the cases. Since this figure was surprisingly low, the full text of papers was examined and we noted that COI were not indexed by WoS if they appear in a specific section separated from the acknowledgements. The presence of COI statements rose to 83% after inspection of the full text of funded papers..Specific conflicts of interest were declared in around 36% of the papers, while 46% included a sentence indicating the lack of COI. It should be noted that a higher presence of declared COI were found in industry funded papers (54%) than in the total set of publications (table 3).

Table 3. Distribution of CARD funded papers by presence of COI statement

	All funded papers		Industry funded papers	
	No.Doc.	*%*	*No.Doc.*	*%*
Declared presence of COI	575	36.58	307	53.86
Declared absence of COI	731	46.50	190	33.33
No COI statement	221	14.06	61	10.70
Not identified*	45	2.86	12	2.11
Total	1572	100	570	100

Note: Data obtained by examining the full text of all papers. * Access to the full text was not available

The different types of COI reported by authors and indexed by WoS (n=374 papers) were grouped into seven categories that are shown in table 4. The most frequent cause of conflict was personal fees (in around 77% of the papers), followed by previous research supported by industry (59%).

Table 4. Distribution of CARD funded papers by type of COI

	No.Doc.	*%*
Personal Fees	287	76.74
Consultant	211	56.42
Advisory board	115	30.75
Speaker honoraria	110	29.41
Lecture fee	92	24.60
Honoraria	56	14.97
Speaker bureau	40	10.70
Trials	27	7.22
Educational activities	15	4.01
Royalties	11	2.94
Grant/research support	220	58.82
Employment	90	24.06
Non-monetary support	71	18.98
Stock/shares ownership	50	13.37
Drugs/equipment supplies	24	6.42
Patents	9	2.41

Note: each paper may present more than one type of COI

A binary logistic regression analysis was conducted to assess what variables contribute to explain the presence of COI (Table 5). The most influential variables were type of funding, industry affiliation and number of funders. We can observe that papers with only private support were 7 times more likely to present COI than those with only public support, while those with industry affiliated authors were 8 times more likely to declare presence of COI. Moreover, having more than 4 funders and receiving foreign support increase the likelihood of COI (OR>4 and OR>2, respectively). It should be also noted that papers published in first quartile journals were more likely to present COI (OR=1.9), while basic research was less likely to report conflicts of interest than the clinical one (OR<1).

Table 5. Results of the binary logistic regression analysis for presence of COI

	B	*Wald*	*Exp(B)*
1st Quartile Journal	0.643***	17.306	1.903
Basic research level	-1.249***	34.182	0.287
Type of funding		80.724	
Only private	1.962***	78.577	7.111
Public and private	0.462*	5.247	1.588
(Reference category=only public)			
No. Funders		44.095	
2-4 funders	0.762***	11.861	2.142
>4 funders	1.529***	42.293	4.616
(Reference category= 1 funder)			
Foreign funding	0.925***	34.572	2.522
Industry Affiliation	2.119***	64.384	8.325
Constant	-2.727***	137.336	0.014

**P* < 0.05; ***P* < 0.01; ****P* < 0.001; R^2=0.40; OR = Odds ratio = Exp(B)

Finally, combining data from authorship and funding support, we observe that industry was involved in 24% of CARD papers (668 papers of 2752). Industry contributes more often with funding support (industry in FA) than with active scientists to the research (industry in address of authors). In fact, 85% (n=570) of industry papers received funding from firms, while only in 36% (n=242) an author affiliated to a company participated in the research (Table 6).

Table 6. Distribution of industry papers by type of industry involvement in the research

	No Papers (%)
Industry only in address	98 (14.7%)
Industry only in FA	426 (63.8%)
Industry in FA and address	144 (21.5%)
Total	668 (100%)

Conclusions

This is an on-going research, but some preliminary conclusions can be outlined:

- Algorithms used by Clarivates to extract funding agencies from the FX section are not always able to discriminate correctly between funders of the current research and those included due to previous links of the authors to industry. Around 20% of false positive data are detected (lower share than in the study of Lewison & Sullivan, 2015), which means that industry funding might be overestimated in FA-based studies. Separate disclosure of funding sources and competing interests in papers would be advisable to avoid this type of errors. In fact, WoS mostly confounds COI with funding support when both are not separated or when only COI is disclosed.
- COI are mentioned in 83% of all funded CARD papers and in 87% of the industry funded papers. In fact, competing interests might exist in all papers with industry participation, so COI statements are less prevalent than expected in these cases, in particular because disclosure of conflict of interest (or a statement indicating that there

are not any competing interests) is at present requested by most journals. Moreover, around 5% of funded CARD papers had an industry affiliation but no COI disclosure, which also suggest under-declaration of COI (Darmon et al. 2018).

- COI are more likely to be disclosed in clinical papers, probably because of the greater involvement of industry in this type of research. Moreover, COI are more likely to be disclosed in the most influential journals —Q1 journals—, which suggests it is aligned with good research practices within the scientific community.
- Industry appears more often in CARD publications as source of research funding than as affiliation of authors, so the combination of authorship and funding-based approaches seems to be advisable to obtain a more comprehensive view of the contribution of industry to research.

The results shown correspond to the analysis of CARD –a clinical field-, which will be compared with data from VIROL –a basic field- (still in progress). Differences are expected since both fields differ in their research practices, funding rate and industry involvement..

As for the interest of this research, it should be noted that transparent and clear disclosure of funding sources and potential COI is important to protect research integrity, improve trust in research and enable the development of a wide range of studies with research policy implications.

Abstract

In this contribution, the authors present the background, main underlying concept, data sources, current state and technical and scientific challenges of the International Register of Book Publishers (IRAP) project. This project aims at the creation of a register of scholarly book publishers collecting, normalizing and aggregating different data sources used for evaluation at the national or supra-national level, both for basic research on scholarly books as publication channel and for the provision of aggregated information to all stakeholders involved with scholarly publishing.

Introduction

Looking at the current international trends in research evaluation in the social sciences and humanities (SSH), we observe tendencies to: a) consider full data sources and different types of research results, not only traditional journal publications and metrics; 2) emphasize the societal impact of research; 3) diversify the sources for analyzing outputs and for obtaining indicators (REF, DORA, Leiden, Metric Tide, ENRESSH Manifesto, etc.). All these tendencies have the potential of recognizing the importance of books for scholarly communication in SSH, as well as the diversity of publishers in which humanists and social scientists publish to reach their relevant audiences. The closeness of SSH to the societies and cultures being studied may often imply publishing in local or national languages and with book publishers from the region or country. The diversity of publishers used in SSH can even be seen as requirement for societal impact and for responsible research and innovation. The diversity of scholarly publishers in a country is needed, not only because they publish scientific knowledge which other publishers with a more international profile would not publish, but because they help fulfil the aims of the research itself by communicating with society. These scholarly publishers have an important role in the broader national book market. Given the concentration in the international book market, where a few editorial groups and imprints amass a large portion of the market (*Coufal, 2017),* it seems necessary to facilitate an adequate safeguard of the existing diversity. In this sense, the defense of the publication of scholarly books in the national framework for the aforementioned reasons should also be accompanied by recognition of those publishers and their contribution to research evaluation processes as the select and improve manuscripts before publishing.

The International Register of Academic Book Publishers (IRAP) is being developed as a response to this situation. The register is an initiative within the COST action ENRESSH which has the more general aim of improving the basis and methods for research evaluation in SSH. IRAP in particular is intended to provide structured, precise and quality information on scholarly book publishers, mainly in Europe, but also in United States, Canada and Latin America with the objective of facilitating scientific research, showing the editorial diversity of the different countries This research in progress paper aims to present the state of the art as well as the methodological challenges involved in the development of this project.

International sources for academic books

The two main commercial products providing indicators for scholarly book publishers and individual books are Book Citation Index (Clarivate Analytics) and Scopus Title Expansion Project (Elsevier). The analysis of aspects such as diversity of languages of publication and countries of origin of the publishers revealed some strong biases towards the inclusion of publishers from English-Speaking countries, particularly those that specialize in STEM fields. (Leydesdorff, L., & Felt, U., 2012; Torres Salinas et al., 2014). These findings are consistent with previous analyses of the bibliometric products for journals from the same companies (Moed 2005; Oppenheim and Summers 2008).

Given the relevance of national languages for the SSH, those biases diminish the suitability of the databases for evaluation purposes at the national level in many European countries. As a result, several initiatives have been developed in recent years in several European countries in order to create information systems that allow the provision of reliable information for evaluation purposes. In example, Norway, Finland, Denmark or Belgium (Flanders region) count with Current Research Information Systems (CRIS) which integrate the whole research publication output of the country, thus providing complete data (Sivertsen, 2016). The publication channels (journals or publishers, in example) are then rated in terms of quality by expert panels (Sīle, L. et al. 2017; Sīle, L. et al. 2018)

Several other initiatives and approaches have been developed in different countries (Giménez –Toledo et al., 2017; Giménez-Toledo et al., 2018). In Spain, ILIA Research Group (Research Group on Scholarly Books, Spanish National Research Council) has developed *Scholarly Publishers Indicators* (SPI) (Giménez-Toledo et al. 2012); it provides information on the perceived prestige of Spanish and non-Spanish scholarly book publishers, information concerning the manuscript selection processes used by the publishers, the thematic specialization and the presence or absence of a given publisher in five information systems (SPI Expanded, from 2016 onwards). These developments are considered as a reference by the main research evaluation agency in Spain (ANECA).

The development of SPI Expanded has allowed the verification of the potential interest of a register of publishers at the European level, which reflects the presence or absence of the different publishers in various information systems used for evaluation purposes, together with attached information on the quality level that the publisher has in each information system. The Nordic countries have developed a 'Nordic List' merging the respective lists of publication channels from their respective countries through a project funded by NORDFORSK. Finally, there is also a clear interest at the European level in the creation of common infrastructures allowing the convergence in terms of information for research evaluation, as Puuska et al. 2018 (p.1) point out.

International Register of Academic Book Publishers (IRAP)

IRAP is a research proposal and technical development for improving the evaluation of scholarly books while preserving national book industries. Taking into account the described context, the relevance of books in SSH, the need of considering diversity in publishing channels and also the growing research on academic book publishing, a working group of ENRESSH COST action[i] is working on the development of the International Register of Academic Book Publishers. It aims at: a) listing all relevant academic book publishers, it is to say, actually used or to be used by researchers b) providing basic bibliographical information c) offering relevant information for research evaluation purposes such us manuscript selection processes or other useful and transparent information to evaluation agencies, academic institutions, etc.

VIRTA pilot project and Nordic List

Methodological issues and current state of the Register

SPI Expanded (http://ilia.cchs.csic.es/SPI/expanded_index.html) is the starting point for building up the register. The following table (1) reflects the key features of the Register at its current stage.

Table 1. Key features of the European Register of Scholarly Publishers at its current state.

Feature	*Values*
Number of distinct publishers	5917
Number of different countries of publishers in the Register	110
Number and percentage of University Presses	766 (12.94%)
Number and percentage of publishers with set of ISBN prefixes	2420 (40.89%)

Table 2. Number of distinct publishers in each source.

Database	*Number of different publishers*
BFI (Denmark)	1371
Publication Forum (Finland)	2747
NSD (Norway)	2891
SPI (Spain)	1097
VABB-SHW (Flanders)	134
Book Citation Index	467
Scopus Title Expansion Program	341

Current sources included in the register are: Book Citation Index (2018); Scopus Title Expansion Program (2018); Norwegian NSD (2018) lists; Finnish Publication Forum lists (2018); Danish BFI lists (2018); Spanish Scholarly Publishers Lists (2014); Flemish VABB-SHW lists (2016). The expansion of the register is presently based on the aggregation of information from other existing lists of book publishers at the national level (linked to databases for evaluation purposes). After these expansions, the project has now come to a stage where the scholarly publishers themselves, represented by their international organizations, can be invited to take part in the project. The project is also in contact with ERIH PLUS, the European register of journals in the SSH, which has for a long time planned to include a register of scholarly book publishers.

The construction of the register implies in the first place a work of presentation of the project as well as establishing contact with those responsible of the national information systems (CRIS or equivalent sources), with national organizations in charge of scientific evaluation and with associations of scholarly publishers.

The inclusion of publishers to IRAP through various authorized methods for data importation and crawling implies several phases of technical treatment of the information, but also some challenges from the point of view of research.

Technical challenges

The aggregation of publishers from different sources requires data cleansing and normalization of publishers' names following the common procedures to that effect. This first normalization is followed by a second, manual stage which has the objective of disambiguation of those cases not identified in the first step. In this second step, the official publisher's names available at the Global Register of Publishers (International ISBN Agency) are used.

The depuration of the data from the different source has presented a series of challenges to its reliability

a) Single name and de-duplication

A single name for each publisher is a desirable condition for a register of publishers. Nevertheless, disambiguation and de-duplication of individual names has been one of the main sources of concern in the process of unifying the different sources. On the one hand, the way in which a given publisher is written can take several forms depending on the inclusion of acronyms and the use of common abbreviations for company type. Also, changes in the names of publishers keeping their activity intact are a source of error in the de-duplication process. In those cases, the main source of information for de-duplicating the names have been the use of the Global Register of Publishers (GRP; https://grp.isbn-international.org/), the largest authoritative list of publishers, developed and updated by the International ISBN Agency. It is a challenge for the development of the Register the identification of an optimal process of disambiguation.

b) Imprints and publishing groups

A second type of error sources are those related to the imprints. Many publishing groups have acquired smaller, independent publishers during the course of their business history. Generally, those previously independent publishers (with their set of ISBN prefixes) are included within the publishing group as imprints. With a single name and a series of ISBN prefixes it is possible to find independent publishers, up to a given date and imprints, from the point in time when the publisher was incorporated or merged into a publishing group. The treatment of such instances requires a case by case review of the publishers' history and, apart from time-consuming, the results are not always clear.

c) Co-editions

Co-editions are a further source of error: the co-editing publishers can be kept as independent publishers, the publisher associated to the ISBN prefix can be kept and the rest discarded or co-publications can be discarded beforehand. It remains a challenge to determine which option would be optimal taking into account the different pros and cons of each approach.

Some research challenges

The CRIS systems used in the Nordic countries and Flanders count with complete data on publication in each country. In the case of Norway, Finland and Denmark, the processes and criteria for the classification of publishers are similar. On the other hand, SPI counts with a completely different approach, based on a survey to Spanish scholars on the prestige of both Spanish and foreign publishers. In the case of Flanders, the GRPC provides a source of recognition of individual books but it interpretation in terms of quality or prestige of the publisher is different from the previous ones. Book Citation Index and Scopus provide a completely different set of indicators, based on citation counts and several other information systems include publishers without indicators allowing the categorization or classification of the publishers. It seems clear that the levels, quality labels, citation counts or prestige of the publishers are not comparable. Nevertheless, the presence or absence of the publishers in the databases is driven by an intentional selection process or, in the case of the CRIS-based systems the publishers are rated in a scale according to their quality level and, on the other, the presence of a given publisher in the highest positions in all sources or, by the opposite, in the lower positions can be understood as a potentially useful information (at least in the extreme cases). The option taken until now is to attach the information on the quality of the publisher to its name when available so that, given the proper conditions for its aggregation or further use; there is the possibility of counting with such aggregated data. Furthermore, as pointed out in Mañana-Rodríguez & Pölönen, 2018, the data on the quality 'national' publishers can be imputed into the judgment-based evaluation systems of other countries which do not count with specific information on the quality of foreign, maybe linguistically or culturally distant publishers.

Other relevant point in the development of the register is how to tackle with the information regarding on manuscript selection processes within publishing houses, a critical issue for research evaluation purposes (Giménez-Toledo, Sivertsen & Mañana-Rodríguez). Opening the debate on standards in academic publishing of books entails, among other issues, questioning of peer review and distinguishing the role book editors from the journals editors. A text is not the same published by a publisher or other. The editors provide quality, correction, style or rigor. A scholarly book is part of a publisher and the 'brand' it prints on it (Calasso, 2015). Pointing out the differences between book publishing and journal publishing is a way of breaking down some inertia in research evaluation and science policy. This topic deserves some research for showing different selection practices within publishing houses –apart from peer review- and their relationship with quality or academic recognition. Results from this research might have positive effects in the development of IRAP.

Future expansion of the Register

Different research projects under development are going to offer results on most relevant academic publishers in Colombia (Giménez-Toledo, 2018) and Brazil (Borges de Oliveira, 2018) and other countries in Latin America. It is foreseen to take these results into account for providing information to the Register.

Also, an initial exploration of the information systems used for evaluation in Croatia, Slovenia, Slovakia and the Czech Republic allows concluding that it would be possible to count with structured sets of scholarly publishers from these information systems. On the other hand, further research on the information systems used for evaluation in other European countries such as the UK, France, Italy, Austria or Germany would provide an opportunity for the broadening of the scope of the Register.

Abstract

The present study aims investigating the adherence of the elite of Brazilian researchers to open access journals as a strategy to publicize their research. The elite was defined as all Brazilian researchers who were receiving in 2016 the most prestigious research fellowship in Brazil. The CNPq productive fellowship 1A is granted to researchers with a very high and continuous performance in scientific publishing and in training human resources as well as a strong visibility inside and outside of Brazil. Information of scientific performance of the elite of Brazilian researchers (n= 1.205) was collected from the Brazilian open directory, Lattes *curriculum*, considering period of 2000-2015. Among the main results, it was found that the largest number of Brazilian articles was published in no-open access journals. Nevertheless, the fraction of articles in open access journals increased from 22.2% in 2000-2003 to 28.6% in 2012-2015 and it was observed an increase in the fraction of researchers with articles in open access journals. The set of results shows that adherence to open access journals by the elite of Brazilian researchers is still low, a worrying scenario considering that this group serves as reference for the rest of the Brazilian scientific community.

Introduction

Since the period known as scientific revolution in the period of 16th – 17th century, communication between researchers has been changing. At that time, books and letters were the main sources for disseminating science knowledge. However, in the middle of the 17th century, scientific journals took on this task, becoming the most important means of registration science knowledge in the following centuries (Meadows, 1974). The success and spread of scientific journals are related to different aspects of the dynamics of scientific communication, including the low cost of publishing in journals, its faster dissemination when compared to books and the insertion of the peer review in the publishing process. Regarding this latter aspect, Zuckerman & Merton (1971) affirmed that process of self-evaluation came to be perceived by scientific community as the mechanism of certification and legitimation of scientific knowledge.

In the 1970s, scientific communication gained its first electronic journal at a time where Internet was still launching. But it was only in the 1990s that many initiatives were organized around the world in order to broaden the number of electronic journals as well as to stimulate researchers to publish in scientific journals in this new format. One of these initiatives was the movement named as Open Access (OA) Movement, which for many authors was born as an alternative against the costly and restricted-access printed journals.

In the last two decades, the OA movement has been structured around some central issues and actions, such as the Budapest Declaration, which states that academic literature should be available online with no costs or other barriers to everyone, including not only the scientists, but scholars, teachers and any other interested person (Budapest, 2002). The Declaration indicates two possible mechanisms to stimulate researchers to join the OA journals: by self-archiving papers at institutional repositories (green road) and by publishing papers in (new) journals committed to the open access ideal (gold road).

It is worth highlighting that the original concept of OA journal, as suggested in the Budapest Declaration, has changed along the last decades, including changes on the aspect of no-payment for authors to publish or for readers to access the articles. In fact, we have witnessed a growth in the number of new OA journals that are supported by article processing charge (APC), especially those that are under the responsibility of commercial publishers. Thus, the expansion of these commercial publishers aimed at the publication of OA journals within different business models such as: immediate open access, hybrid open access, open access late and open promotional access (LAAKSO et al, 2011).

The idea of the article processing charge (APC) as the main source for funding OA journals gained prominence after the publication and diffusion of Finch Report in 2012. This report, entitled "Accessibility, sustainability, excellence: how to expand access to research publications", clearly lists and discusses some recommendations in favour of golden road journals but with APCs, which should be the main strategy for guaranteeing "both effective and sustainable over time, for expanding access to the published findings of research" (Finch, 2012). Initially, APC would display a cost price, as it would cover the primary costs for editing and publishing the on-line journals. Nevertheless, APC values display very high nowadays, what maybe, in contrast to Finch Report, an actually barrier for the consolidation of OA journals, since authors, institutions or governs will have to assume this charge.

An estimate of the OA journals expansion can be obtained from the Directory of Open Access Journals (DOAJ), a repository launched in 2003 with only 300 open access journals. Today, it indexes more than 12.000 titles from almost 130 countries, including Brazil that is among the top-three position in the DOAJ ranking of countries with the highest number of indexed titles: United Kingdom with 1.378, Indonesia with 1.335 and Brazil with 1.242 (DOAJ. 2018).

Brazil's outstanding position in the DOAJ ranking seems to be a result of some national initiatives, as the foundation and expansion of the Scientific Electronic Library Online (SciELO) during the last two decades, as well as some actions led by the Brazilian Institute of Information in Science and Technology (IBICT), such as the introduction of the Electronic Journaling System (a software developed for helping the creation and management of electronic journals) and the launching of the Brazilian Manifesto to Support Open Access to Scientific Information in 2005. These initiatives (and others not described here) widespread open access in Brazil.

Considering the striking presence of Brazilian journals in the DOAJ ranking and, at the same time, the growth of the country's scientific production on an international mainstream (Leta, Thijs, Glänzel, 2013; Sandoval-Romero, Mongeon & Larivière, 2018), we started a large project to investigate to what extend Brazilian scientific community is supporting the OA journal model. The project is based on the premise that publishing in restricted journals (that is, those known as mainstream) or publishing in OA journals would result in different amounts of prestige for researchers or, as conceived by Bourdieu (2004), it would be expressed differently in the accumulation of scientific capital.

Scientific community is strongly structured around a special research grant in Brazil, named CNPq scientific productivity (PQ - the abbreviation in Portuguese) fellowship. The PQ fellowship is granted to a small portion of the whole Brazilian scientific community, that is, those with outstanding levels of scientific and/or technological performance. There are five PQ fellowship categories 1A, 1B, 1C, 1D and 2 granted for active researchers, being the first category considered the elite of Brazilian researchers. In 2016, the number of these PQ fellowships summed 14,342, varying from 1,205 in PQ 1A to 8,037 in PQ 2 (CNPq, 2018).

The present study focuses on Brazilian researchers who received the PQ 1A fellowship in 2016, the highest CNPq - PQ fellowship category. Researchers granted with this fellowship displays a very high and continuous performance in scientific publishing and in training human resources as well as a strong level of collaboration and visibility at the national and international scientific arena. Researchers awarded with this fellowship have some exclusive benefits, such as coordinating research calls with high amount of resources that may be used not only for purchasing equipment but also for supporting students. Such type of benefit increases the gap between the elite of Brazilian researchers (the most top PQ fellowship category, PQ 1A) and the whole Brazilian scientific community, which summed around 200 thousands researchers in 2016 (CNPq, 2016b). In fact, this fellowship acts a sign of distinction (Bourdieu, 2004) and reinforces the hierarchical structure of science in Brazil. Hence, considering the central role of this select group not only as leaders of Brazilian science but also as the group that directly influences the country's science and technology policies, the present paper aims investigating whether they are publishing in OA journals as a strategy to publicize their research. This goal is based in the following research questions: do the elite of Brazilian researchers publish in OA journals? Is this selective and influential group of Brazilian researchers adhering to this new publication format?

It is important to highlight that, for the purposes of this project, OA journals are those whose content is fully available to the Web since its first day of publication, they are catalogued at DOAJ and may or may not be supported by APCs.

Methodology

The information of scientific performance of all 1.205 researchers with the PQ-1A fellowship in 2016 was collected in May 2016 from Lattes *curriculum*. This is a Brazilian open directory created in the 1990’s to compile personal information, academic trajectory, scientific production and other information of all Brazilian scientific community (CNPq, 2018)

Based on the list of names and the webpage of each curriculum, we used the ScriptLattes software (Mena-Chalco & Cesar Junior, 2009) to extract a couple of data from all 1.205 curricula, including: name, sex, area of research, institution of affiliation and details of each publication they published in the period 2000-2015 (coauthors, year, ISSN and source name). It is relevant to underline that only information of documents publish in scientific journals were considered. Simultaneously, a list of the OA journals available at DOAJ was downloaded, including also some additional information, such as ISSN and e-ISSN, country where the journal was edited, whether the journal charges processing article fees, etc.

After cleaning and standardizing the names of the journals and their respective ISSN (or e-ISSN), the list of journals where the 1.205 Brazilian researchers published in the period 2000-2015 was crossed with the list of DOAJ. This was a semi-automatic process and it allowed the classification of each publication of Brazilian researchers as being published in an OA journal, with or without APC, or in a restricted journal.

After all, an excel file was created with personal and academic information as well as with information on scientific publications, especially the indication of published in an open access or in a restricted journal. In order to identify possible changes in the tendencies in publishing of this select group, the data are presented in periods of four years: 2000-2003, 2004-2007, 2008-2011 and 2012-2015. Also, researchers were classified in five groups of adherence to OA journals, 0-20%, 20.1-40%, 40.1-60%, 60.1-80% and 80.1-100%, that are interpreted as very low, low, intermediate, high and very high adherence, respectively.

Results

In order to observe the adherence of the elite of Brazilian researchers to OA journals, the following sessions focus in two main analyses: the proportion of articles in OA journals and the proportion of researchers that publish in OA journals along the studied period.

Number and proportion of articles in OA journals

As shown in table 1, the total number of articles published by the 1.205 Brazilian researchers who received the PQ-1A fellowship, considered here the elite of Brazilian scientific community, increased almost 50% (from 26,363 to 39,067) in the whole period. Such increase was mainly pushed by the 91% of growth of articles published in OA journals in the period (from 5,842 to 11,186).

The higher increase observed in the total number of articles in OA journals led to an increase in the share of these articles when compared to articles published in restricted journals: from 22.2% to 28.6% versus 77.8 % to 71.4%.

Although the number of articles in restricted journals represents almost 2.5 times the number of articles in OA journals in the last period, it is clear that there is a movement towards broadening the adherence to open access journals among this select group of Brazilian researchers.

Table 1. Number and percentage of articles in open access journals and in restricted journals authored by the elite of Brazilian researchers* in four periods.

Period	*Restricted*	*Open#*	*Total*	*Restricted (%)*	*Open (%)*
2000 – 2003	20,521	5,842	26,363	77.8	22.2
2004 – 2007	25,721	8,016	33,737	76.2	23.8
2008 – 2011	28,403	10,193	38,596	73.6	26.4
2012 – 2015	27,881	11,186	39,067	71.4	28.6
2000 – 2015	102,526	35,237	137,763	74.4	25.6

*Includes 1.205 Brazilian researchers that received in 2016 the PQ-1A fellowship, the most prestigious fellowship granted in the country.# Open access journals are defined as those listed in DOAJ.

Although the number of articles in restricted journals represents almost 2.5 times the number of articles in OA journals in the last period, it is clear that there is a movement towards broadening the adherence to OA journals among this select group of Brazilian researchers. Considering this trend, we decided looking closer to the 35,237 articles published in OA journals by Brazilian elite researchers in the whole studied period (2000-2015) to find out whether or not they are supported by article processing charge (APC).

As it can be observed in Figure 1, the studied group publish predominantly articles in OA journals with no APC. In the two first periods, the number of articles in these journals is more than 10-fold the number of articles with APC. Nevertheless, it is clear that, in more recent periods, the number of articles published in OA journals with APC increased substantially. Thus, it is possible that in a near future, the number of articles in OA journals with APC will surpass the number of articles without APC. Such movement is, in a certain way, in accordance with the discussion promoted by Finch Report in which the commitment to promote OA should be to publish in journals with APC.

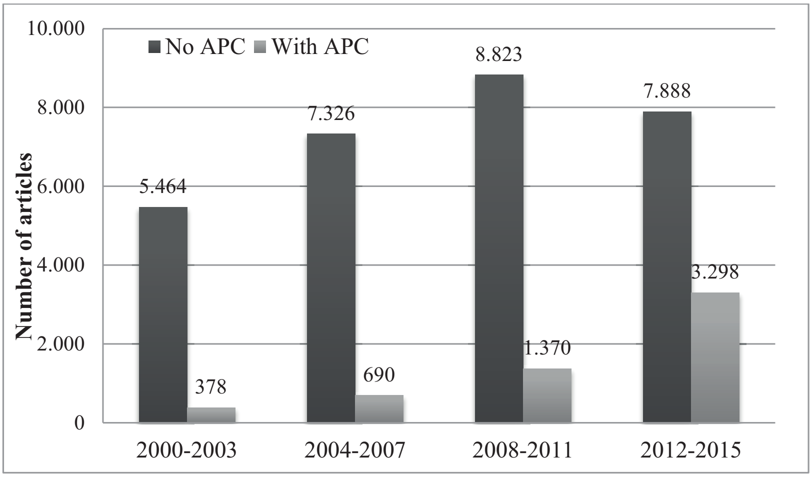

Figure 1. Number of articles in open access journals supported or not by APC (article processing charge) authored by Brazilian researchers* in four periods.

* Includes 1.205 Brazilian researchers that received in 2016 the PQ-1A fellowship, the most prestigious fellowship granted in the country.

In order to better characterize articles published in OA journals, with or without APC, in terms of country where they are edited and their main thematic, we elaborated a list of the top-10 journals with the largest number of articles in both types of journals.

Table 2 presents the top-10 open access journals with no APC and their respective number of articles published by PQ-1A fellowship. The number of articles published in the top-10 journals listed in table 2 sums 1,491 in 2000-2003, 1,719 in 2004-2007, 1,655 in 2008-2011 and 1,057 in 2012-2015, representing 27.3%, 23.5%, 18.8% and 13.4% of the total of each period, respectively. Such decrease in the share indicates that articles are dispersed in a larger number of OA journals in more recent periods.

Looking closer in this list, one first observation is that they are all edited in Brazil and most of them are classified under the fields of agriculture/animal sciences, biological sciences and health sciences, with a single exception, Quimica Nova, which is from Chemistry.

A completely different profile is observed at the top-10 open access journals with APC and the respective number of articles published by the elite of Brazilian researchers (table 3).

Although the amount of number of articles published in these journals is relatively smaller when compared to those of table 2, that is 300 in 2000-2003, 460 in 2004-2007, 629 in 2008-2011 and 1,611 in 2012-2015, they represent higher shares of the total of articles published in OA journals with APC each period, that is, 79.4%, 66.7%, 45.9% and 48.8%, respectively. Such decrease in the share of these journals indicates that articles are dispersed in a larger number of OA journals in more recent periods, but it is important to highlight that articles are still concentrated in a few number of OA journals with APC, a trend that was not observed in the previous analysis (table 2).

Table 2: List of top-10 open access journals with no APC where the elite of Brazilian researchers have published more in four periods.

	2000-2003	*2004-2007*	*2008-2011*	*2012-2015*
1	Brazilian Journal of Animal Science (457)	Brazilian Journal of Animal Science (459)	Brazilian Journal of Animal Science (451)	Pesquisa Veterinária Brasileira (147)
2	Brazilian journal of medical and biological research (199)	Brazilian journal of medical and biological research (213)	Química Nova (179)	Cadernos de Saúde Pública (136)

10	Brazilian Journal of Veterinary Research and Animal Science (83)	Revista de Saúde Pública / Journal of Public Health (95)	Brazilian Journal of Medical and Biological Research (93)	Molecules (86)

* Includes 1.205 Brazilian researchers that received in 2016 the PQ-1A fellowship, the most prestigious fellowship granted in the country. Number of articles in each journal is indicated in parenthesis.

The list of top-10 open access journals with APC shows that the select group of Brazilian researchers tends to publish mostly in journals classified under the fields of biological sciences, health sciences and agriculture. Also, they publish more in national OA journals with APC, especially in the first two periods. In the 2012-2015 periods, Brazilian researchers published in 7 out of the top-10 journals are edited overseas. It is worth noting the contribution of articles published in PLOS' journals, particularly the PlosOne, which articles represent 31% of the total articles published by this group in OA journals with APC in 2012-2015.

In the previous analysis (table 2), we have not observed a trend toward international journals, suggesting that the process of choosing OA journals with APC by Brazilian researchers is in favor of journals with more global visibility. On the other hand, the central role of Brazilian OA journals in both analyses was indeed expected since the country displays one of the highest numbers of OA journal according to DOAJ.

Table 3: List of top-15 open access journals with APC where the elite of Brazilian researchers have published more in four periods.

* Includes 1.205 Brazilian researchers that received in 2016 the PQ-1A fellowship, the most prestigious fellowship granted in the country. Number of articles in each journal is indicated in parenthesis.

Distribution of researchers that publish in OA journals

As seen in the previous section, the number of articles in OA journals authored by the elite of Brazilian researchers has been increased since 2000, representing almost 29% of total articles published in 2012-2015 period (table 1). This result raised the following question: is such increase related to the adherence of a higher number of researchers that started publishing in OA journals? In order to answer this question, we analysed the distribution of Brazilian researchers according to the number of articles they have published, in restricted or open journals, in each of the four periods of study, as shown in Table 4.

Considering the distribution of researchers by articles published in restricted access journals, it is possible to note that the majority of researchers published 11 or more articles in each period. The most relevant observation, however, is that the distribution of researchers changed very little from one range to another, the exception is the 6-10 articles range, which percentage of researchers reduces along the periods.

A different trend is observed for the distribution of researchers by articles published in OA journals. The largest fraction of researchers is found in the 1-5 articles range, but this fraction was been clearly reduced over time. Such change led to an increase in the number of researchers started publishing more articles in OA journals, especially in 21-50 articles range, where the percentage of researchers has jumped from 4.6% to 11.1%.

Table 4 – Percentage of Brazilian elite researchers* according to number of articles they published in open access journals and in restricted journals in four periods.

	Number of Articles	*2000 - 2003* *%*	*2004 - 2007* *%*	*2008 - 2011* *%*	*2012 – 2015* *%*

*Includes 1.205 Brazilian researchers that received in 2016 the PQ-1A fellowship, the most prestigious fellowship granted in the country

The data presented in Table 4 indicates that, in fact, more researchers from this selective group are choosing OA journals to diffuse their work. Nevertheless, we questioned whether such change towards OA journals is also observed if we consider the whole set of articles each of these researchers published.

In order to answer this question, we calculated the percentage of articles in OA journals in relation to the total articles each of the 1,205 researchers published in each period. Researchers were classified into five groups of adherence to OA journals: very low (0-20%), low (20.1-40%), intermediate (40.1-60%), high (60.1-80%) and very high (80.1-100%); the first group includes researchers with the lowest fraction of articles in OA journal, while the last group those with the highest fraction.

As shown in Figure 2, researchers with very low adherence comprise the largest group in the four periods. However, it easy to note that this group is been reduced in numbers (from 737 to 520) and in percentage (from 61% to 42%) over time. At the same time, the low and intermediate groups, especially the latter, were enlarged in numbers and percentage, a result that indicates that this select group of researchers is more and more diffusing their research in OA journals.

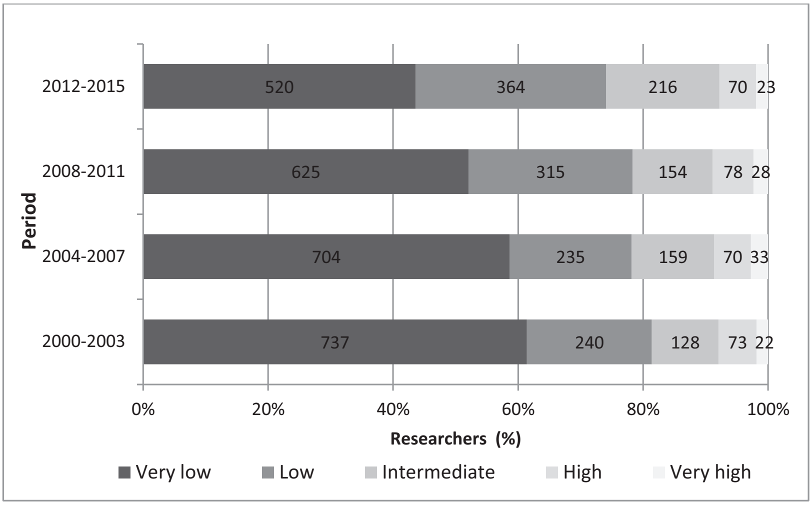

Figure 2: Distribution of Brazilian elite researchers* according to range of adherence to open access journals considering the whole number of articles they published in each period.
(very low = 0 to 20%; low = 20.1% to 40%; Intermediate = 40.1% to 60%; high = 60.1% to 80%; very high = 80.1% to 100%)

Conclusion

Considering the main objective of this study, the set of results presented in previous sections shows that the adherence of the elite of Brazilian researchers is still low, but with a tendency of growing, especially within OA journals with APC. Thus, these results, focused in the adherence of the elite of Brazilian researchers in OA journals, suggest that they are more plural and diverse in choosing the journals.

In spite of this positive movement, the adherence to OA journals among this select group is still far below of that observed in recent literature. Using a combination of sources, Archambault *et al* (2014) have found that around 70% Brazilian scientific production was published in OA journals. One possible explanation for such difference between results found in Archambault's work and results found in this paper includes (a) the extent of sources (different sources versus Lattes only), (b) the period of analysis (2008–2013 versus 2000 – 2015) and concept for OA (wide-ranging versus only DOAJ). In a more recent study, Wang et al (2018) have found that Brazil was among the top-three countries with the highest number of publications in OA journals indexed in WoS in the period from 1990 to 2016; according to the authors, Brazilian share reached 41% in 2014.

It is also noteworthy that increasing adherence to OA journals by the elite of Brazilian researchers seems to be more and more related to the OA model with APC. Such trend is in accordance with the Finch Report guidelines (2012), which points to APCs as a strategy to expand access to the new knowledge published in scientific journals.

The preference for publishing in journals with restricted access as well as the increasing choice for journals with OA supported by APC may be a consequence of a lack of knowledge about the original OA model or even a biased understanding about the quality of OA journals, as pointed in some studies (Nicholas, Huntington & Rowlands, 2005; Rodriguez, 2014). As for Brazilian scientific community, Furnival & Silva-Jerez (2017) surveyed 643 researchers with a position in a Brazilian university discarded the lack of knowledge. The authors found that most of the interviewed display a good level of understanding about the main principles of OA. They declared they are in favour of publishing in OA journals, but whenever possible, they choose higher impact journals. This type of choice supports the notion that scientific capital, expressed here by the impact factor of the journal, as a factor that drives the scientific environment.

Investigating the factors that influence Brazilian researchers is the focus of a study that is in course within our group. We believe that some personal factors (such as age and sex) and academic (such as field and institution) may have an impact in choosing to publish (or not) in OA journals. Also, we are expanding the data analysis, considering the publishing dynamics of Brazilian researchers awarded other PQ fellowship categories as well as researchers without PQ fellowship. In this case, the hypothesis is that the lowest is the prestige of a researcher, the highest is the ratio of papers he/she published in OA journals. Both strategies will allow us to elaborate a better comprehensive view of the adherence to OA journals by the Brazilian scientific community within a theoretical framework that includes some concepts, mainly, accumulation of prestige/scientific capital and power maintenance in science.

By now, the preliminary results shown in this paper suggest that OA journals is not yet used as a strategic means for disseminating scientific knowledge produced by the elite of Brazilian researchers. By one side, it is a surprising finding since Brazil is one of the countries with the largest number of OA journals. By other side, it is an expected finding if we assume that the *status quo* of this selective group is maintained by the journal prestige where they publish, a quality that is not, in general, observed or imputed to OA journals.

Abstract

Since the topic of "women in research and innovation" has been on the agenda for decades and numerous measures have been implemented at both national and international level to improve the equality of women in the research and innovation systems, it is still unclear under which conditions which measures are most effective. Even less research has been carried out into the effects of better representation of women in terms of (responsible) research and innovation results. Within this paper, an evaluation approach shall be presented, which starts exactly here and uses case studies to show how the concrete implementation of the evaluation model in practice takes place. Furthermore, the results of on the case studies are presented that show how national gender equality measures addressing Higher Education Institutions as well as Research Performing Organisations do not only achieve a better representation of women within these organisations but do also contribute to scientific excellence.

Background and purpose of the study

Despite all efforts undertaken in the past there is no comprehensive and rigorous analytical framework to consider all of the relevant variables in gender equality issues, although there have been a number of European Commission projects such as PRAGES, GENDERA, GenSET, STAGES and GENOVATE, which have explored the gender equality (GE) dimension with different foci. While all these previous studies have illustrated numerous evaluation approaches, concepts, indicators etc. to provide examples of measuring different kinds of impacts, a clear understanding of the mechanisms between different gender equality-related policy initiatives and interventions (inputs) and outputs/results is still not available. In order to address these challenges, EFFORTI (Evaluation Framework for Promoting Gender Equality in Research & Innovation), an EU funded project, aims to clarify the mechanisms between gender equality inputs and the expected results not only on gender equality itself, but also on research and innovation (R&I). The evaluation framework provides the theory and tools for analysing how gender equality-related interventions contribute to the achievement of the three European Research Area’s main objectives on gender equality and how those achievements affect the desired outcomes of (responsible) research and innovation. The uniqueness of the evaluation framework is that it goes beyond conventional research and innovation indicators, taking into account also evaluation dimensions like providing answers to the Grand Challenges and the promotion of Responsible Research and Innovation.

With the rise of the idea of evidence-based policy-making (e.g. Nutley et al. 2002; Solesbury 2001; Sanderson 2002), expectations have grown regarding the use of scientific evidence in policy-making. At the same time, establishing causal relationships between policy interventions and observed changes poses a theoretical challenge as well as empirical and methodological problems. One approach to address these challenges is the theory-based impact evaluation approach (TBIE): In theory-based impact evaluation (TBIE), causality is often defined as a problem of contribution, not attribution. "Why and how" questions are typically being asked instead of "how things would have been without" as counter-factual approaches do. The goal is to answer the "why it works" question by identifying the theory of change ("how things should logically work to produce the desired change") behind the program and assessing its success by comparing theory with actual implementation. The "theories" to be investigated on how gender equality and R&I outcomes interrelate (intervention logics), which in turn link the allocation of resources to the achievement of intended results and finally impacts are still to be developed. These might be complemented by academic theories about public interventions and already existing empirical evidence from former evaluations and impact assessments. The actual results of GE policies will depend both on policy effectiveness and on other context variables. Context factors are organizational structures and cultures, as well as national and regional structures, capabilities and policies. The application of a theory based impact evaluation approach will allow us to take these different levels of influences on policy effectiveness - mechanisms and context - systematically into account. Furthermore, it allows us developing context sensitive and policy specific theories of change.

Methodological Approach

Drawing on already developed and applied indicators in gender equality and R&I research (RIO Observatory, OECD STI Scoreboard etc.), but also on recent studies on RRI indicators (Ravn et al. 2015a, 2015b, European Commission 2015), we carried out a comprehensive desk research as a basis for the collection of a preliminary list of relevant indicators. The team first identified the most relevant indicators according to literature review; clustered these indicators into different categories, dimensions and sub-dimensions, which are based on GE-related literature and smart practice examples implemented in different organisations and contexts; and finally grouped these indicators according to an evaluation logic model. The indicators are differentiated between input, throughput, output, outcome and impact aspects. For each aspect, the indicators are illustrated at micro/individual or team level, meso/organisational level and macro/policy or country level.

The indicators are based on the collection and review of “smart practices” implemented in Europe and beyond. The identification of smart practices was based on an assessment of the practices that are relevant, effective and efficient in the context that they operate in as to their quality of both evaluation and measurement (Kalpazidou Schmidt et al. 2017c). Smart practice examples evaluated measures of different nature and length: some constituted large national programmes with a long-term perspective, while others were of a more limited character. The selection of smart practices was based on the criteria of (1) the quality of the implemented measures, and (2) the impact of the measures. The quality of the measures was assessed based on the parameters of relevance, effectiveness, efficiency, and sustainability of the interventions, while the impact of the measures was assessed in relation to its subjective/objective dimension (Kalpazidou Schmidt & Cacace 2017). Furthermore, we used the existing evidence on the impact of gender diversity on different benefit areas and integrated the respective indicators into the evaluation framework too (for the overview on benefits, see see Bührer / Yorulmaz 2019):

Table 1. Overview on the relation between gender equality and performance

GENDER AND SCIENTIFIC BENEFITS	GENDER AND ECONOMIC BENEFITS
Interdisciplinary & thematic diversity ***Better dissemination of research results and higher share of citations*** ***Social responsiveness and scientific excellence***	***Increased creativity and organizational innovation*** ***Better strategic decision-making & overall competitiveness*** ***Better financial performance*** ***Positive employment effects & job satisfaction*** ***More effective recruiting and retention*** ***Increased organizational attractiveness, brand image and reputation*** ***Better networking and access to customers and markets*** ***Stronger adherence to ethics and rules of conduct***
GENDER AND ENVIRONMENTAL BENEFITS	**GENDER AND SOCIETAL BENEFITS**
More sustainability initiatives ***Higher environmental consciousness in consumption*** ***More eco-innovations***	***Combating gender discrimination through symbolic commitment to equality*** ***Empowerment and confidence*** ***More corporate social responsibility*** ***More supportive and philanthropic behaviour***

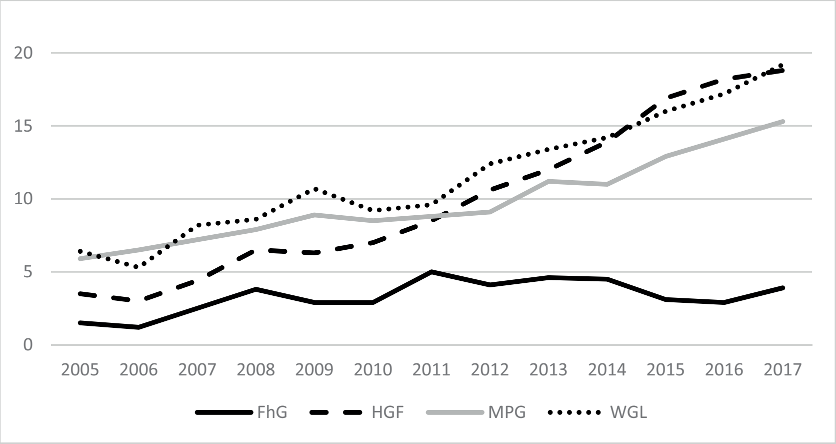
Synthesising the typologies developed by Kalpazidou Schmidt and Cacace (2017) and the fields of action identified by the GENERA project and building on further theoretical and empirical experiences, we developed an intervention typology. Examples of impact stories were developed for a broad spectrum of these intervention types in order to provide examples of the mechanisms regarding intervention intentions and to provide a common framework for understanding the multi-faceted interventions of the cases that will serve as a testing ground for the further development of the tentative evaluation model.

Case Study approach for validation purposes

The EFFORTI intervention logic model forms the conceptual basis for the case study work. The Intervention Logic Model considers inputs, throughputs, and outputs, as well as outcomes and impacts of the former two. The model also aims at showing how, once achieved, these objectives or effects can further affect desired R&I effects such as the number of patents and number of publications and citations, but also new R&I effects, such as providing answers to grand challenges and further promoting RRI. Additionally, the model includes three levels, i.e. team level (research quality, productivity, innovative outputs, and other RRI effects), organisational/ institutional level (workplace quality, recruitment capacity, efficiency, RRI orientation, competitiveness), and country/ system/ policy level (intensity, productivity, ERA orientation, etc.). However, some interventions will most likely overlap between different levels, which was taken into account in the development of the toolbox (EFFORTI Conceptual Evaluation Framework, D3.3, Kalpazidou et al. 2017.8). After having developed a first tentative evaluation framework, a series of case studies is foreseen to validate and further improve the model. Yin (1994.13) defines a case study inquiry as one that *"Investigates a contemporary phenomenon within its real-life context, especially when the boundaries between phenomenon and context are not clearly evident."* Therefore, the case study method lends itself to research where contextual factors are highly pertinent to the phenomenon of study (ibid). Case studies as a method have also been used extensively in evaluation research. We used the case study method to inductively build on and validate the evaluation framework. The multiple case study work shed light on those factors and mechanisms that shape and influence the effects of gender equality interventions in R&I on research and innovation outputs. It also attempted to explain how the national/ science system context influences the intervention in terms of the main contextual elements as well as the main agendas, strategies, and policies that shape the intervention.

Case Study Example Germany: The case study examined whether two of the major German flagship programmes to increase the participation of female researchers in the German science system, the "Women Professorship Programme" and the "Pact for Research and Innovation", have actually increased the number of women, especially in leadership positions. In a second step, we analysed whether such an assumed increase influences the publication patterns of authors with German affiliation. The case study was based on literature and desk research as well as bibliometric analysis using Scopus.

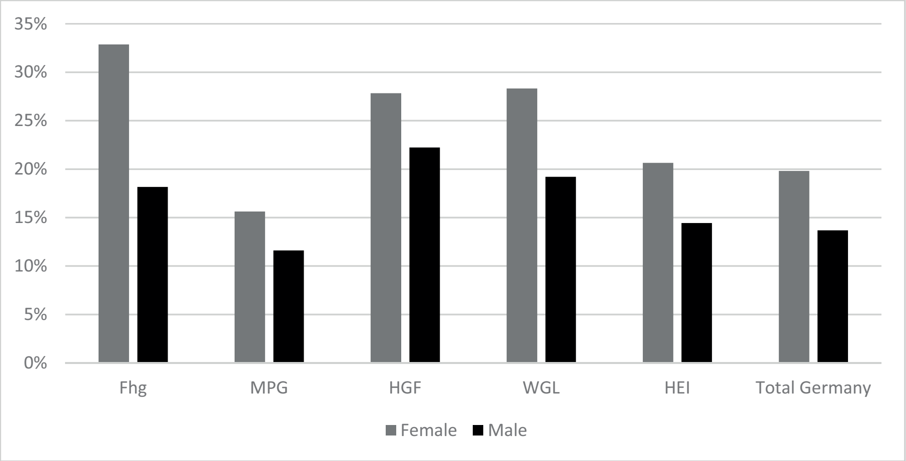
Figure 1. Share of women in leading positions at German non-university research institutions 1992-2016



Source: GWK 2012, GWK 2018

The most important result was that the number of women in research has indeed increased significantly in recent years (see Figure 1) and, accordingly, more women are the (co)authors of scientific publications (see Figure 2). In particular, it can be seen that quality indicators such as citations and excellence rates are high for female authors. This enables us to show that more women in the science system not only bring about a "gain in justice", but also a concrete scientific benefit.

Figure 2. Average annual growth rate in publications by women and men in Germany between 2005 and 2016



Source: Elsevier - Scopus; Fraunhofer ISI calculations.

Discussion and conclusions

Based on a thorough analysis of the relevant knowledge in gender equality, evaluation as well as science and innovation research and the structured analysis of smart practice examples, an evaluation framework has been developed which was then used for the conduction of in total 19 case studies in seven EU countries (Austria, Denmark, France, Germany, Hungary, Spain and Sweden). The case studies cover a broad range of gender equality interventions, from mentoring instruments over structural change approaches up to incentives for integrating gender aspects into research and innovation projects.

Our approach of using a theory-based evaluation framework is appropriate even though it has hardly been possible to measure concrete research and innovation outcomes and impacts of the GE programmes under consideration directly. However, the example presented above show that, not least due to the two big national GE interventions, the role of women academics in the German publication landscape has changed significantly over the past 15 years and there has been a clear increase in the number of (co-)publications by female authors. Furthermore, although the overall number of women has also increased significantly since the introduction of the flagship promotional measures of the Women Professorship Programme and Pact for Research and Innovation, it has not risen to the same extent as women's participation in scientific publications. This means there are clear benefits for Germany in terms of scientific outputs from an increased proportion of women in its scientific workforce.

Our investigation has not yet been able to establish a direct link between the launch of the programmes and the improved representation of women in the different bibliometric indicators. However, we have good reasons to assume that the programmes have at least contributed not only to the higher shares of women within the research performing organisations, but - as a long-term impact - also to improved female publication patterns, especially in terms of citations and excellence rates.

One critique, however, can be that the theory of changes emphasizes differences between male and female researchers and might lead to the promotion of stereotypes. Furthermore, the work with log frames is rather linear and only partly suitable for complex environments, as we are fully aware.

Abstract

The purpose of this paper is to provide a comprehensive picture of open access publishing in Finland. Data consists of the complete national peer-reviewed output of 48177 articles and books from 14 Finnish universities in 2016-2017 stored in the VIRTA Publication Information Service. Each publication record contains an indication if it is openly available as Gold or Hybrid OA and/or if it is deposited in OA repository. Using this data, we investigate the share of openly available outputs across fields, as well as journal and book publishing, and analyse the open access status of all 10342 publication channels (journal/series and book publishers) used by Finnish researchers. We also examine the utility of international open access information sources, DOAJ and Bielefeld list for OA journals, and Sherpa/Romeo for self-archiving policies, in estimating the potential for open availability of peer-reviewed outputs, as well as the importance of the largest international commercial publishers in light of these comprehensive national data.

Introduction

In 2016, the European Union member states agreed to "open access to scientific publications as the default option by 2020 and to the best possible re-use of research data as a way to accelerate the transition towards an open science system" (Council of the European Union, 2016). The European Commission supports the transition with a strong open science agenda (European Commission, 2018). Most recently, a group of European research funders known as cOAlition S (which includes Finland's largest research funder, the Academy of Finland) plans to make immediate open access and unrestricted use requirements for all published research funded by the signatories by 2020. This concern, in the first place, journal articles, while a longer transition period is admitted for peer-reviewed book publications.

Finland, like many European countries, is currently developing national strategies and incentives for advancing open access. In 2014-2017, the Ministry of Education and Culture funded a national project, the Open Science and Research Initiative, which set ambitious national targets for the share of openly available publications: 65% in 2017, 75% in 2018 and 100% in 2020 (Ilva, 2017b). According to European Open Science Monitor, the share of OA in Finland is 41.6%, so it ranks 19th out of 36 countries compared. Recently, the Finnish government has approved a new funding model for allocating core-funding annually to universities in 2021-2024. A publication indicator (Pölönen, 2018) will distribute 14 % of the funding, and the publication points based on publication type and channel are multiplied by 1.2

if the peer-reviewed output is openly available (independent of OA mechanism or embargo length). Meanwhile, the Ministry has invested in development of comprehensive national publication data that supports, in addition to the performance-based research funding system (PRFS), monitoring of open access publishing in Finland (Ilva, 2017a).

All countries face the challenge that the vast majority of peer-reviewed outlets used by researchers do not support Gold open access publishing. Many outlets allow individual papers to be made openly available on the publisher website, however, this hybrid OA model is considered unsustainable due to increasing costs and only partial open availability of outputs (Piwowar et al. 2018). It has also been observed that publishing in journals that allow self-archiving (Green OA) does not automatically mean that publications are actually deposited in open access repositories, highlighting a gap between potential and uptake (Laakso, 2014; Björk et al., 2014). Green journals may impose embargoes for the peer-reviewed post-print and publisher version, making them not compliant for example with the Plan S requirements.

Directory of Open Access Journals (DOAJ) and Sherpa/Romeo are the most frequently used information sources to identify Gold and Green OA channels. Nevertheless, even these sources may not provide full coverage of Gold and Green channels. Bielefeld university, for example, provides an ISSN-Matching of Gold OA Journals based – in addition to DOAJ – also to the Directory of Open Access Scholarly Resources (ROAD), PubMed Central (PMC) and Open APC (OAPC) (Wohlgemuth et al. 2016). It is, however, an open question to what extent these existing sources cover the whole variety of publication channels used at the national level, or help estimating the level of open availability of peer-reviewed outputs.

Given that the five largest international commercial publishers account for more than half of the journal output indexed in Web of Science (WoS) (Larivière et al. 2015), most attention at both international and national level is focused on pressuring and/or negotiating with these publishers for open availability of publications. But as Larivière et al. (2015) point out, WoS purports to cover only the most cited international subset of scholarly journals. Especially in the social sciences and humanities (SSH), WoS coverage is seriously wanting due to the importance of national language and book publishing (Kulczycki et al., 2018). In many SSH disciplines, the majority of journal articles are published in national or regional outlets not indexed in WoS (van Leeuwen & Sivertsen 2014; Sivertsen 2016). In addition, up to one half of peer-reviewed outputs in Humanities, and around one-third in the social sciences, are book publications (Engels et al. 2018).

The challenge of implementing and providing open access at a national level has various aspects of which we highlight three. Firstly, analysing what share of national output is published as OA and in how many and what kind of channels. This cannot be easily calculated on the basis of international databases such as WoS or Scopus, or Google Scholar (Martín-Martín, 2018). The implication is that only countries in which current research information systems with full coverage of the SSH publications (Sīle et al, 2018) have been developed can provide an accurate picture of publication patterns and OA publishing in all fields and across publication types. Such an analysis is important as a basis for tailor-made science policy instruments. Secondly, implementing OA at the national level requires infrastructure, tools and resources for open publishing (Sivertsen, 2018). It is an important prerequisite in the ongoing process of flipping journals to the OA model. One possible solution is to use the Open Journal Systems developed by the Public Knowledge Project, to provide a translation of the system into the national language, to provide some training materials, and to ensure resources and create incentives for flipping national journals to the OA model (Ilva, 2018). Another option is to build a national OA platform from the very beginning, as in Croatia (Stojanovski et al, 2009) or in Québec (Larivière and Macaluso, 2011). Thirdly, the challenge of open access at the national level is to provide all mentioned analyses and materials, infrastructure, and platforms also for the peer-reviewed book publications. Scholarly monographs, book chapters and edited volumes play a key role in the social sciences, humanities, and law domains (Montgomery et al, 2018). Thus, not only journal articles but also books should be fully integrated into the OA scholarship.

In this paper we investigate the extent of such challenges by means of a comprehensive analysis of open access publishing in Finland based on complete national publication data. The national information sources remain under-exploited in analysis of open access publishing, and have focused predominantly on journal publishing (Ilva, 2017b; Kronman, 2017; Mikki, 2017; Mikki et al., 2018). Our main research questions are:

1. What is the share of openly available peer-reviewed journal and book publications across fields of science in Finland?
2. How many journals/series and book publishers do Finnish researchers use for publishing peer-reviewed outputs across fields of science, and how large is their share that provides for full, partial or no open availability of Finnish outputs?
3. How large is the share of journals/series that have been identified in VIRTA as OA channels, and what share of these outlets are indexed in DOAJ and Bielefeld list?
4. How large is the share of journals/series that are indexed in Sherpa/Romeo, and does the self-archiving policy influence the share of Finnish outputs in those journals that are openly available?
5. How large is the share of book publishers that are identified in VIRTA as OA channels or have permitted self-archiving?
6. To what extent do the largest international commercial publishers dominate the publishing of Finnish researchers, and are there differences between fields?

Data and Methods

The data consists of unique peer-reviewed outputs published in 2016-2017 that the 14 Finnish universities have reported to the Ministry of Education and Culture and that are stored in the VIRTA publication information service (Sīle et al., 2017; Sīle et al., 2018; Pölönen, 2018). In VIRTA, co-publications of Finnish universities appear as duplicates, however, duplicates are automatically identified on the basis of publication information and indicated in the data. In this study, we use deduplicated publication counts. For each publication, the reporting university has indicated the publication type, OECD field of science, peer review status and open availability. This study includes peer-reviewed articles in journals, books and proceedings, as well as monographs and edited works from all fields of science. For the year 2017 the data collection is not yet entirely complete.

The years 2016 and 2017 have been selected because universities have indicated the open availability of peer-reviewed outputs according to renewed definitions (Ilva, 2017a). Firstly, it is indicated for each output if it is openly available in either Gold or Hybrid OA publication channel. Secondly, it is indicated if the publication is openly available in an OA repository. Information on embargoes or OA licenses, however, is not available in the data. Consequently, it is possible to establish if a peer-reviewed publication is openly available in an OA or Hybrid channel, deposited in a repository, or both. The open availability of a publication can be verified using the URL provided in its metadata. The validation of openly available publications takes place at the universities, and involves both researchers and data collection personnel from the university libraries.

In VIRTA, the publication channel – journal/series or book publisher – of each peer-reviewed output has been identified by matching the publication's bibliographic metadata to the Publication Forum authority list of publication channels. The authority list covers all journals/series and book publishers actually used by researchers affiliated with the 14 Finnish universities. Journals/series include mostly journals but also some book series with ISSN code, as well as some conference proceedings without ISSN. Book publishers mostly have a registered ISBN. For journals/series with ISSN, the Publication Forum channel register contains

the name of the publisher retrieved from the International ISSN Centre. We have complemented the ISSN Centre data with publisher information in the Scopus journal list. It is also indicated if the channel is included in the Directory of Open Access Journals (DOAJ), the Bielefeld list of open access journals, and what the self-archiving policy is according to Sherpa/Romeo.
In 2016-2017, the 14 Finnish universities published a total of 48177 unique peer-reviewed outputs in 10342 publication channels, of which 91.9 % are journals/series and 8.1 % are book publishers (Table 1). 16.5 % of outputs are published with book publishers, while 83.5 % are published in journals/series. Only 62 % of all peer-reviewed outputs are published in journals indexed in Scopus and 52 % in WoS journals (Figure 1). There are, however, large differences between fields in the share of outputs in journals/series, as well as in Scopus and WoS coverage.

Table 1: Number of journals/series and book publishers and their share of outputs by main fields of science

Field of Science	Publication channels			Outputs		
		Journals/ Series	Book publishers		In Journals/ Series	In Book publishers
	N	%	%	N	%	%

Results

Identification of open access status of publication channels based on VIRTA

In VIRTA, there is some evidence of open availability of outputs for one-half of the 10342 publication channels that Finnish researchers have used in 2016-2017 (Table 2). But there is considerable variation in the share of the Finnish outputs that are openly available in different channels. In roughly one-fourth of the channels (24.7 %) all Finnish outputs are openly available, and in one-fourth (25.5 %) of the channels the open availability is only partial. Half (49.8 %) of the publication channels do not seem to have any publications reported as being openly available. This pattern is observed, more or less, in all the main fields, although the share of channels providing no form of open availability is somewhat larger in SSH. This is because open availability is more restricted in the case of book publishers than journal/series.

Table 2: Number of journals/series and book publishers and their share of outputs by main fields of science

Field of science and channel type	Publication Channels (N)	Share of openly available outputs in channel					
		100 %	<100% >=75%	<75% >=50%	<50% >=25%	<25% >0%	0 %
Natural sciences	3750	20.5 %	2.8 %	9.3 %	12.4 %	12.1 %	42.9 %
Engineering	1888	16.4 %	2.8 %	7.5 %	11.5 %	15.7 %	46.2 %
Medicine and health	2541	24.1 %	1.6 %	9.1 %	12.0 %	11.2 %	42.0 %
Agriculture and forestry	404	21.8 %	3.0 %	6.2 %	10.6 %	19.1 %	39.4 %
Social sciences	3307	24.6 %	2.7 %	9.6 %	10.0 %	7.9 %	45.2 %
Arts & humanities	1782	22.6 %	3.3 %	7.8 %	8.1 %	7.2 %	51.0 %
All fields	10342	24.7 %	1.8 %	7.9 %	8.6 %	7.2 %	49.8 %
- Journal/series	9500	25.6 %	1.8 %	8.1 %	9.1 %	7.1 %	48.3 %
- Book publisher	842	14.8 %	1.0 %	6.2 %	3.7 %	8.2 %	66.2 %

Of 9500 journals/series the Finnish researchers used as publication channels, 2074 have at least one peer-reviewed output stored in VIRTA that has been indicated as being openly available in a Gold OA channel (21.8 % of journals/series). In the case of 281 journals/series, outputs are marked as being openly available in both Gold and Hybrid OA channel (3 %), so there is some ambiguity about the OA status of the channel. Outputs from 1137 journals/series have been indicated as being openly available in a Hybrid OA channel (12 %). There are further 1416 journals/series, from which outputs are indicated in VIRTA as being openly available in an OA repository (14.9 %) but not in a Gold or Hybrid channel. For 4592 journals/series used by Finnish researchers we have no indication of any form of open access in VIRTA (48.3 %). The share of journals/series identified as Gold OA channels is smaller for the largest commercial publishers than for the other publishers (Table 3).

Table 3. Type of open access of journals/series by publisher as identified in VIRTA

Publisher	Publication channels	Gold OA channel	Gold or Hybrid channel	Hybrid OA channel	Only self-archiving	No indication of open access
	N	%	%	%	%	%
Elsevier	1373	7.2 %	3.3 %	20.2 %	22.1 %	47.2 %
Springer Nature	605	10.4 %	3.0 %	23.0 %	13.2 %	50.4 %
Wiley-Blackwell	595	8.2 %	2.2 %	18.2 %	16.0 %	55.5 %
Taylor & Francis	553	7.6 %	1.8 %	11.9 %	19.9 %	58.8 %
Sage	273	9.9 %	0.7 %	7.7 %	27.1 %	54.6 %
ACS	46	6.5 %	6.5 %	34.8 %	23.9 %	28.3 %
Other	6055	29.6 %	3.1 %	8.4 %	12.3 %	46.6 %
All journals/series	9500	21.8 %	3.0 %	12.0 %	14.9 %	48.3 %

For the book publishers there is no comprehensive source on OA-status or self-archiving policy, such as DOAJ and Sherpa/Romeo for journals. The VIRTA data indicates, however, that 186 different publishers have at least one output registered as being openly available in a Gold OA channel (22.1 % of the publishers). Outputs from 6 book publishers are indicated as being openly available in both Gold and Hybrid OA channels (0.7 %), so there is ambiguity about the OA status, and 4 book publishers have been identified as Hybrid channels (0.5 %). There are further 89 book publishers, of which outputs have been indicated as being self-archived in an open access repository (10.6 %) but they are not openly available in the publisher website. For 557 book publishers used by Finnish researchers there is no indication of open availability of any outputs (66.2 %). The share of Gold OA channels is about the same for both journals/series and book publishers, however, the availability of Hybrid OA and self-archiving options appear much more limited in the latter case.

There is a considerable difference in share of openly available outputs according to open access status of the channel, as well as according to publications channel type (Figure 2). The share of outputs indicated as being openly available in VIRTA is largest in the identified Gold OA channels (79 %), followed by Hybrid OA channels (31 %) and smallest in journals/series with only self-archived outputs (26 %). The same is observed in case of book publishers, however, the overall share of openly available outputs is much smaller.

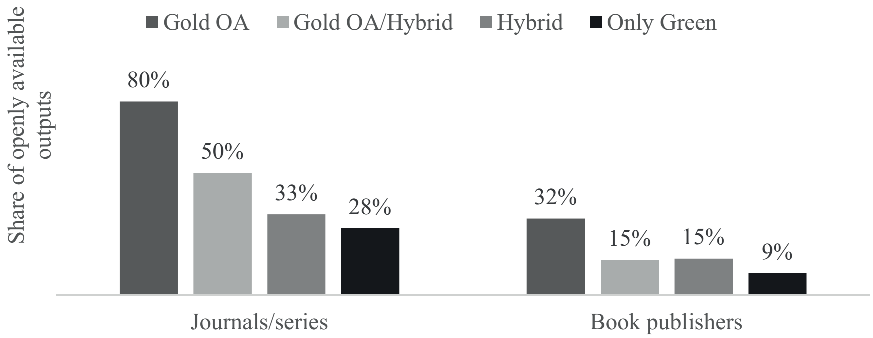

Figure 2. Open Access Status of publication channels as identified in VIRTA and share of openly available outputs.

Comparison of VIRTA based open access status of journals/series with DOAJ and Bielefeld list

Of all 9500 journals/series used by Finnish researchers, 1237 are Gold OA journals indexed in DOAJ with or without a green tick (13 %) (Table 4). Furthermore, 372 journals/series are included in the Bielefeld list of open access journals but are not indexed in DOAJ (3.9 %). Comparison with VIRTA data suggests that inclusion of journal/series in DOAJ and the Bielefeld list is a good predictor of open access, as 96 % outputs from channels in DOAJ and 78 % from channels in Bielefeld are actually indicated in VIRTA as being openly available. For journals/series outside DOAJ and the Bielefeld list, the share of openly available outputs is considerably smaller (25 %), yet as large as 54 % in case of those journals/series indicated as Gold OA channels.

Together, DOAJ and the Bielefeld list cover over 60 % of all journals/series identified as Gold OA channels based on the VIRTA data (including Gold/Hybrid OA journals). Combining all information sources it is possible to identify a total of 2553 potential Gold OA journals, of which 48 % based on DOAJ, 15 % based on the Bielefeld list, and an additional 37 % based on VIRTA (Figure 2). It is noteworthy that 37 % of all potential Gold OA channels are not included in either DOAJ or the Bielefeld list (it has not been possible for us to manually verify their Gold OA status).

Table 4. Comparison of VIRTA based Open Access Status with DOAJ and Bielefeld list, and share of openly available outputs.

	Publication channels	Outputs	Openly available outputs	Openly available outputs
	N	N	N	%
DOAJ	1237	6013	5765	95.9 %
+Bielefeld	372	1249	973	77.9 %
Not in DOAJ or Bielefeld list	7891	32977	8289	25.1 %
All publication channels	9500	40239	15027	37.3 %

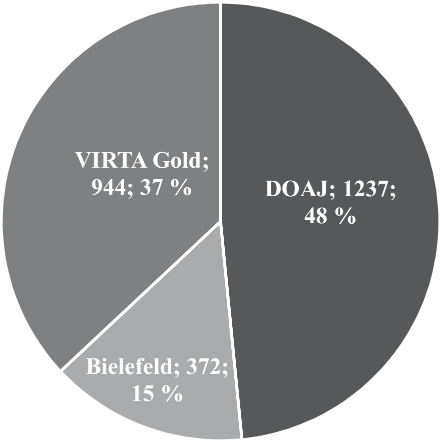

Figure 3. Share of potential Gold OA journals identified based on DOAJ, Bielefeld list and VIRTA

Comparison of Sherpa/Romeo self-archiving policies of journals/series with DOAJ and Bielefeld list and open availability of outputs in VIRTA

Sherpa/Romeo codes indicating the self-archiving policies cover 7537 journals/series (79 % of all journals/series) used by Finnish researchers (Table 5). Sherpa/Romeo includes almost all DOAJ journals (95 %), and a considerable share of Bielefeld listed journals (43 %). Overall, however, the inclusion of journals in Sherpa/Romeo is not a very good predictor of open availability of outputs, the share of which in VIRTA is practically the same as in the case of journals not included in the Sherpa/Romeo service (Figure 3). The share of openly available outputs is much larger for channels included in DOAJ or the Bielefeld list, than for the other channels included in Sherpa/Romeo. Availability of the Gold route clearly has resulted in more complete open availability of outputs than the Green route. The differences in self-archiving policy do not make a great difference, especially if we look at journals/series not in DOAJ or the Bielefeld list.

Table 6. Sherpa/Romeo codes and share of openly available outputs.

Sherpa/Romeo self-archiving policy	Publication channels	
	N	%
Green (publisher version)	5034	53.0 %
Blue (post-print)	361	3.8 %
Yellow (pre-print)	1346	14.2 %
White (none)	267	2.8 %
Gray (unknown)	529	5.6 %
Not in Sherpa/Romeo	1963	20.7 %
All publication channels	9500	100 %

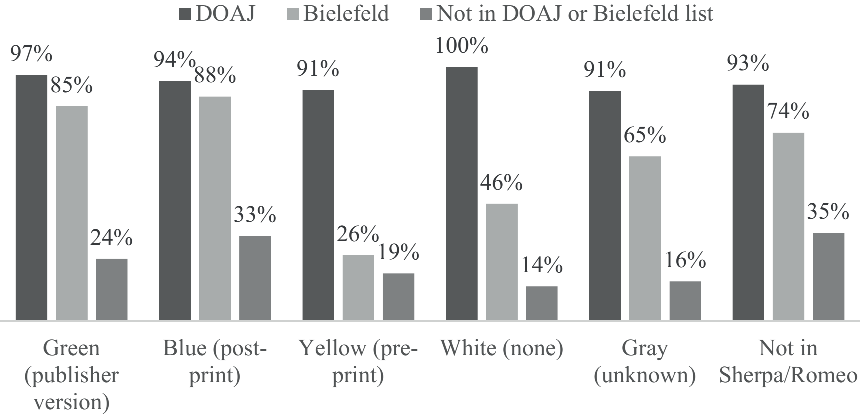

Figure 3. Sherpa/Romeo codes and share of openly available outputs in DOAJ and Bielefeld listed journals

The importance of the largest international commercial publishers and open availability of the outputs across fields

Publication channels owned by Elsevier account for 20.1 % of the 14 Finnish universities' journal outputs in all fields of science counted together (Table 6). Next come Springer Nature (12.8 %), Wiley-Blackwell (9.2 %) and Taylor & Francis (6.8 %). Sage and the American Chemical Society (ACS), which are often also considered among the "big" commercial publishers, account for 2.3 % and 1.9 % respectively. Taken together, these publishers account for 53.1 % of the journal output. This is consonant with studies based on Web of Science data, even though national VIRTA data includes many journals/series not indexed in WoS. If we take into account also peer-reviewed conference articles and book publications, these publishers' joint share of Finish output diminishes to less than half (44.3 %). VIRTA data also suggests that the commercial publishers included in this study are most dominant in Medicine and Agriculture, and least dominant in the social sciences and especially humanities. Thus, our study corroborates the findings of Larivière et al. (2015) concerning the humanities being the field least dominated by the big publishers. In our analysis, however, social sciences is among the least, not the most, dominated fields (this holds true even if we limit analysis to journal articles).

Of all Finnish 2016-2017 peer-reviewed outputs one-third is openly available (33.6 %) and two-thirds are not openly available (66.4 %) (Table 7). The share of openly available outputs is somewhat smaller in case of the large commercial publishers (except Springer Nature) than other publishers. The share of openly available outputs is also larger among journal articles than conference and book publications. Overall, the differences between fields are not great. Nevertheless, natural sciences (39 %) and medicine (37 %) have the largest, while SSH (30 %) and especially engineering (26 %) have smallest share of openly available outputs (Figure 4).

Table 6. The six largest commercial publishers' share of outputs by field of science and publication type

Field and publication type	Outputs	Elsevier	Springer Nature	Wiley-Blackwell	Taylor & Francis	Sage	ACS	Other
	N	%	%	%	%	%	%	%
Natural sciences	15230	17.5 %	17.8 %	8.1 %	2.3 %	0.4 %	3.0 %	50.9 %
Engineering	6647	22.5 %	8.9 %	4.3 %	2.9 %	0.9 %	2.4 %	58.1 %
Medicine and health	10189	19.9 %	17.7 %	13.1 %	6.3 %	2.4 %	0.6 %	40.1 %
Agriculture and forestry	900	27.6 %	12.2 %	10.1 %	5.4 %	0.4 %	0.7 %	43.6 %
Social sciences	10608	8.6 %	8.7 %	3.9 %	14.0 %	4.2 %	0.0 %	60.5 %
Arts & humanities	5920	2.1 %	4.5 %	1.4 %	8.7 %	1.2 %	0.0 %	82.1 %

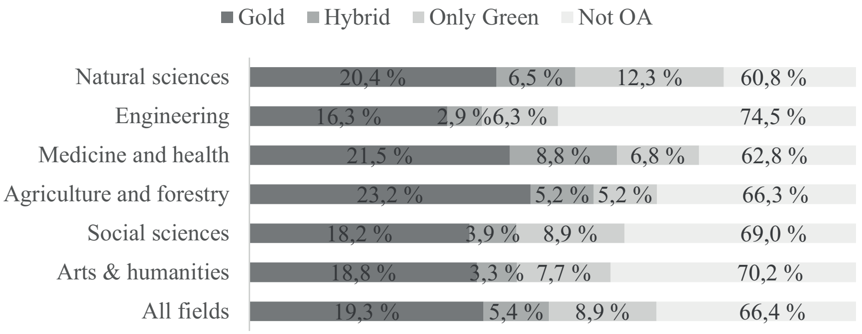

Figure 4. Type of open availability of outputs by field of science

Discussion and conclusions

The international data sources (Web of Science and Scopus), which are most often used for monitoring open access publishing, privilege journal outputs and STEM fields. The national publication data stored in the VIRTA publication information service from the 14 Finnish universities, including 48 177 peer-reviewed outputs from 2016-2017, provides a more complete picture of open access by also including book publications as well as all SSH journal publications. Scopus journals cover only 62 %, and WoS journals 52 %, of all these outputs. Taking all fields and publications types into account, the share of openly available outputs is 34 %. For 25 % of the outputs open availability is provided in a Gold or Hybrid channel, while 9 % are openly available only in repositories. The differences between fields in the share of openly available outputs range from 39 % in the natural sciences to 26 % in engineering.

The Finnish researchers used 10 342 different publication channels as outlets, including 9500 journals/series and 842 book publishers. In 25 % of the channels all Finnish outputs are openly available. In 25 % of the channels, however, the open availability is only partial, and in case of 50 % of the channels no openly available outputs have been reported in VIRTA. It is important to remember that we rely here on universities' self-reported OA status of publications. These results mean that, for Finland to achieve the target of open availability of all peer-reviewed outputs in the near future, around 5000 currently used channels should either be replaced with alternative open access channels or should flip to the required gold or green open access publishing models. Around 2500 channels already provide for open availability of some outputs, hence closing the gap between potential and uptake is the key.

The majority of journals/series used by the Finnish researchers (79 %) have a self-archiving policy registered in Sherpa/Romeo. Analysis of the share of Finnish outputs published in these journals shows that a relatively small share is openly available, irrespective of the self-archiving policy indicated with colour code, unless the outlet also provides open availability via Gold OA (DOAJ-indexed or Bielefeld listed journals). The share of openly available outputs is only slightly larger in the case of Hybrid OA channels than in channels permitting only self-archiving. Our results confirm that there indeed is considerable potential for advancing open availability via Green route (Laakso 2014; Björk et al. 2014). It remains to be seen if open access incentives, such as the extra-weight for openly available publications in the Finnish universities' core funding-model, help to increase the uptake.

As expected, publishing in DOAJ-indexed journals is a good predictor of open availability of outputs. However, only 13 % of the journals/series used by the Finnish researchers are indexed in DOAJ. These account for 15 % of all peer-reviewed journal outputs, and 38 % of all openly available journal outputs (including book publications, the shares are 12 % and 35 % respectively). A total of 944 journals/series identified in VIRTA as OA channels are not covered in DOAJ or Bielefeld list. It has not been possible for us to investigate if these journals/series might meet the DOAJ criteria. Nevertheless, our findings point at considerable gap in the information sources on OA channels. Combining all OA information, it was possible to identify 2553 potential Gold OA journals, of which DOAJ covers 48 % and the Bielefeld list additional 15 %. Our findings suggest that relying on external information sources, such as DOAJ, in the identification of open access publications may not result in complete picture of Gold OA publishing.

We also investigated the importance of large international publishers. Elsevier, Springer Nature, Wiley-Blackwell, Taylor & Francis, Sage and American Chemical Society account for 53 % of the Finnish peer-reviewed journal output, and 44 % of all outputs including conferences and book publications. In all, their dominance appears less pronounced than in analyses using Web of Science data, especially in case of humanities as well as social sciences (Larivière et al., 2015). This means that negotiations with the largest international publishers can provide only partial solution to advancement of open access, which – especially in the SSH – depends on open access publishing models adopted by large variety of relatively small journal and book publishers operating in national context (Ilva, 2018; Late et al., 2018).

The VIRTA publication data provides valuable information on the open availability of peer-reviewed book publications compared to journal articles (conference articles as a group is a mixture of both these publication types). The share of articles in books, monographs and edited works that are openly available is smaller (17 %) than that of journal articles (39 %). Nevertheless, 186 different book publishers (22 % of all publishers used by the Finnish researchers) are identified in VIRTA as Gold OA channels providing for open availability via publisher website at least to some of the outputs. Hybrid and self-archiving options appear, however, more restricted in case of book publishers. Our findings highlight the need for international register of academic/scholarly book publishers that would contain information – like DOAJ – on their peer-review practices, as well as open access status and self-archiving policies.

In all, we conclude that national publication data can provide valuable information on the open availability of peer-reviewed outputs. To enhance comprehensive and comparable monitoring of open access we recommend development of well-structured and comprehensive national and international publication information sources.

Knowledge Utilization and Open Science Policies: Noble aims that ensure quality research *or* Ordering discoveries like a pizza?

Abstract

Open Science has been a rising theme in the landscape of science policy in recent years. The goal is to make research that emerges from publicly funded science to become findable, accessible, interoperable and reusable (FAIR) for use by other researchers. Knowledge utilization policies aim to efficiently make scientific knowledge beneficial for society at large. This paper demonstrates how Astronomy aspires to be open and transparent given their criteria for high research quality, which aim at pushing knowledge forward and clear communication of findings. However, the use of quantitative metrics in research evaluation puts pressure on the researcher, such that taking the extra time for transparent publishing of data and results is difficult, given that astronomers aren't rewarded for the quality of research papers, but rather their quantity. This paper explores the current mode of openness in Astronomy and how incentives due to funding, publication practices and indicators affect this field. The paper concludes with some recommendations on how policies such as making science more "open" have the potential to contribute to scientific quality in Astronomy.

Introduction

Making science more open has been a rising theme for policy stakeholders at international (e.g. European Commission[i] and United Nations[ii]) and national levels (e.g. Netherlands Organisation for Scientific Research; NWO[iii]). The goal is to make research that emerges from publicly funded science to become *findable, accessible, interoperable and reusable (FAIR)* for use by other researchers. Stakeholders like the NWO and European Commission acknowledge that the way science is conducted is fundamentally changing due to the sophisticated digital technologies available. Often these 'open' policies are part of a more general 'knowledge utilization' policy, which aims to efficiently make scientific knowledge beneficial for society at large under the imperative of the *Three Os – Open Innovation, Open Science* and *Open to the World.* The aim of the paper is to give recommendations of what 'open' policies would need to consider in order to support FAIR publication in Astronomy, while at the same time encouraging quality in the knowledge production process. This investigation includes in what way astronomers value openness and how current policies encourage openness and research quality.

New policies may come with new incentives and new ways to measure whether certain goals have been achieved. These may not only come with the aspired effects, but also with "unintended consequences" (drawing back to the notion of "unanticipated consequences of purposive social action"; Merton, 1936) such as quality discrimination. The notion of unintended consequences has been a long-standing debate in the sociology of (e-)valuation as well as in the contexts of notions of "reflexivity", "performativity", self-fulfilling prophecies or “retroaction”. All of these approaches share a common denominator, namely that there seems to be a disjunctive moment between intention, action not only on the micro-level of the individual actor, but also on the level of agglomerations spanning from communities of practice up to society at large. It might therefore be valuable to approach the issue of discourse on a certain topic, in this case “open science” with the notion of what in the most simple formula be termed “feedback” and at the same time the relation between justification and critique that structures part of that discourse.

One aspect of justification and critique becomes apparent in questions how to measure and ensure high-quality of knowledge production in the context of “*Accountability*” and “*transparency*”. Both concepts are closely associated with producing and monitoring metrics (Espeland & Vannebo, 2008). This is because quantification is one means to constitute social entities as things that last and are comparable. As such, the goal of quantification is to enable objectification and to master uncertainty. Through objectification, both a political space and a measuring space, are co-constituted in which things can be compared (Desrosieres, 1998). It permits scrutiny of complex or disparate phenomena in ways that enable judgment (Espeland & Stevens, 2008). Hence, quantification offers a shared language and replaces trust in people with “trust in numbers” (Porter, 1995). Quantification therefore is seen as one mode of de-localization of valuation practices. Quantitative metrics, such as indicators to measure scientific productivity, *commensurate*, which is the act of using numbers to rate and rank, creating a specific type of relationship among objects. Commensuration is one of the most consequential uses of numbers (Espeland & Stevens, 2008), because it turns describing numbers into prescriptive ones. Commensuration attributes meaning to numbers.

Effort or how individual researchers *perform* cannot be monitored efficiently so assessment cannot be based upon it and therefore, a scientist is rewarded and funded for quantitative achievement instead (Rosenberg & Nelson, 1994). The same holds for *usefulness* of science. Not only is it difficult to measure usefulness, but there is also a tension between the ever increasing demand for *societal relevance* (e.g. Bouter, 2008) and the risky nature of basic research. The problem of commensurability of usefulness also becomes apparent, when we observe typical means of addressing usefulness or impact in research evaluation. One of the most notable examples being the narrative form of signifying impact in the Research Excellence Framework (REF). Yet, as elaborated before, there are social forces that adhere to the idea of measurability. Basic research is the human’s endeavour to understand the unknown and as such it is by definition risky (Stephan, 2012). When societal relevance is measured in applicable outputs, and decisions must be made about distribution of researchers amongst research fields, economic pressure to produce such outputs can arise. This may lead to a tension between demonstrating its usefulness to society, on the one hand, and not being able to guarantee that due to the risky nature of research, on the other hand. For research fields that perform mainly basic research, such as Physics and Astronomy, this pressure to justify their societal relevance might be especially high, since results of basic research may have a delay in leading to ground breaking technological developments or theories. More applied sciences, “where the products of research are highly profitable, such as medicine, biotechnology, genetics and military research” (Bourdieu, 2004), face a different economic pressure, the expectation to produce more and better.

Measures that initially may have been designed to describe behaviour can easily be used to judge and control it, due their commensurative character. Measurement intervenes in the social worlds it depicts, as measures are *reactive & performative*; they cause people to think and act differently. Hence, numbers can also exert discipline on those they depict and disciplinary practices define what is appropriate, normal, and to what we should aspire (Espeland & Stevens, 2008). Foucault (1977 & 2003) links statistical practices to "*governmentality*", a term to describe how the government uses numbers to influence citizens so that they fulfil those government's policies. He describes discipline as a mode of modern power that is continuous, diffuse and embedded in everyday routines.

The performative character of indicators leads to the conclusion that policies have constitutive effects on how science is done (Dahler-Larsen, 2014). In other words, indicators and rewards introduced by policies can shape the process how knowledge is produced in science. The fact that indicators commensurate, where all difference is transformed into quantity (Espeland & Stevens, 2008), leads to the argument that their use to assess scientific quality gives rise to an "evaluation gap". This is a term coined by Wouters (2017) to acknowledge a discrepancy between the notions of scientific quality as perceived by researchers of a field and as measured by indicators. In order to meet the targets set by indicators, scientific quality may be sacrificed. This can have "unintended consequences" such as goal displacement, gaming, information overload, questionable authorship practices, unhealthy competition and aversion to risky/innovative projects (Rushforth & De Rijcke, 2015; Laudel & Gläser, 2014).

As outlined above, basic research is under the pressure of demonstrating its societal relevance. While astronomy asks highly fundamental questions, which inspire both scientists and the public at large, Astronomy faces a crisis to demonstrate its usefulness. That is shown by the fact that one can find a large number of flyers and commentaries on the internet and elsewhere explaining why astronomy is important (e.g. Rosenberg et al., 2013). Applications from Astronomy are rather invisible for the public, due to two reasons. First, as outlined above, basic research usually doesn't find immediate societal usefulness. An example is applying the theory of general relativity to enable precision in the Global Positioning System (GPS). Second, uncovering the laws of nature, such as the theory of general relativity, is Astronomy's primary goal, resulting applications are secondary. Nevertheless, technology invented for space exploration often leads to surprising applications on Earth, so-called spin-offs, such as innovations in dental care and breast cancer detection. Hence, there is a tension between needing an output due to economic pressures and doing basic research for its own sake that entails dead ends and no immediate usefulness. Additionally, large and expensive (international) observing instruments involve large collaborations and the use of (open) archives and huge datasets. For these reasons, Astronomy is such an interesting case to study the significance of indicators in its usefulness crisis and their relevance in this tension relationship. To which extent indicators shape the conditions under which astronomers produce knowledge, is what needs to be answered when developing new policies.

Methods

This research[iv] consists of semi-structured interviews[v] and a document analysis. The interview sample was targeted such that the interviewees represent a variety of nations, career-status and research areas. 4 faculty members, 2 postdocs, 1 PhD and 2 Master students from Leiden Observatory (Sterrewacht) were chosen who work in cosmology (2), exoplanets (1) and observational (radio) astronomy in different subfields (6). The Master programme at the Sterrewacht is very research intensive, requiring the student to write two Master theses in total, which is the reason why they are also interesting subjects for this study. In order to shed light on what effects policies have on the field, questions were developed such that an astronomer's definition of quality versus what is measured by indicators can be studied. Next to the meaning of openness and data sharing, topics include career steps, project funding, exposure to assessments, research evaluation, the publication and funding system, different stages of the knowledge production process – from planning, via doing the research to publishing – and the meaning of quality. Each topic was introduced by one overarching question, followed by several potential follow-up questions.

The participating researchers were invited via email and all names are anonymized. All interviews, 80-100 minutes in length, were fully transcribed into electronic form, summarised and coded) according to Grounded Theory. These codes represent themes which emerged by combining sensitivity towards existing literature on constitutive effects of indicator use with insights from the data.

The interview data were complemented with a document analysis of materials collected online or made available via the informants, including CVs of the interviewed researchers, annual reports (1998 to 2015), (self-) evaluation reports of the Dutch Astronomy institutes and their umbrella organisation NOVA. The documents informed the following analysis, however the document analysis itself is not part of this study and can be found in the original report of the project[iv].

In the *Results* section direct quotes of the interviewees will be given between double quotation marks.

Results

The astronomers' stance to openness and effects of current policies

In order to understand what policies related to 'opennes' would mean for Astronomy, we must first ask what data and research results mean to an astronomer. My study found that astronomers generally conduct science for the sake of curiosity and "pushing knowledge forward" (Faculty Member 4). For them, publications are not their priority, but rather a means to publicise their results in order to advance the field in three steps:

> "You have a new science idea. You have asked the question clearly and well, with a well-defined […]. And you have written a paper which demonstrates you have answered that question […]. And you have written it in such way that a non-expert in that field can read it and understand what you have done. […] If it's a crap written paper, then that's crap research – I don't care how brilliant the answer is, if they can't communicate it through a paper or through a presentation, then that's bad research."
> (Faculty Member 4)
>
> "And ahh … if that was not so important [to get papers out] I would probably not bother so much … I mean I would still publish my papers because I – it gives a different motivation to it, right? As a scientist you just want to publish your papers, because you are a scientist and you think this is important for science: 'This is the result, this is what defines the process of science'." (Faculty Member 1)

Rather, it is in the astronomers' interest to share data and results to get knowledge "out to the community" (Faculty Member 1). "To know and understand better" (Postdoc 1) and communicate this knowledge to the community is what makes up an astronomer's intrinsic motivation to conduct research. For an astronomer, the definition of high-quality research is based on this motivation. I found three quality criteria:

- Asking an important question for the sake of understanding the universe better and to push knowledge forward.
- Using clear, verifiable and sound methodology.
- Clear communication of the results so the community can make use of them.

From these criteria it is apparent that astronomers' motivation in doing science is not for some direct societal impact, since they are dedicated to fundamental research which might only find applications decades later (Stephan, 2012).

> "Well, academic quality has always been relatively clear. It has to be verifiable and clear, unbiased etc. But there is these days … a tendency to look at the value of science in terms of economic output, it's called '*valorization'*. And I am totally uninterested in that […]. It is always nice if you find applications that are useful […]. Why not? But that's not why we do it." (Faculty Member 1)

On the other hand, openness in terms of disseminating the knowledge gained does fit within astronomers' values and definition of quality. To understand how 'open' policies could have positive effects on openness in Astronomy, and whether they could at the same time encourage scientific quality, we must first look at the effects of current policies.
This study found factors for extrinsic motivation that drive research in Astronomy as well as the intrinsic factors. Extrinsic motivation arises from what the evaluation system values through its indicators. Astronomers report that *first author publications*, *citation rates* and *number of acquired grants* are what determine their value as a researcher. Since the future career of an astronomer is dependent on these factors, there is a shift from the initial motivation to publish for the sake of disseminating knowledge, to the "need to publish" (e.g. Postdoc 1 & Faculty Member 1). This results in publication pressure and lower quality papers.

> "Your job prospects will depend on this like quantity rate, with which you are publishing." (PhD Candidate)
>
> "It's a system problem I think. Erm, I try to do quality research, but I do feel sometimes that I end up publishing because I have to publish.", "I wish we could just focus on more like quality papers instead of quantity papers." (Postdoc 1)

Observational astronomers are found to be particularly affected by this pressure as compared to theoretical astronomers. On the one hand, they produce data with telescopes which are essential for the knowledge production process in Astronomy. On the other hand, this data is a form of output that is reportedly not valued in evaluations. To produce data, observational astronomers need to compete for limited *observation time* at telescopes and then 'be lucky' to have the right weather conditions. Once granted, observation time does count like received funding in an astronomer's CV. However, non-detections are more common than detections and 90% of non-detections are not publishable. Hence, observational astronomers face the risk to fall through the cracks of metrics in every step of their knowledge production process.

> "So it's essentially [that] negative results are considered as failed research by the community. […] And on that side I disagree. […] So there is always information to be taken from research that is well conducted. Given that the research is using state of the art data, and state of the art methodology, whatever the result is, should be interesting." (Postdoc 2)
>
> "Non-detections. [...] It's just really hard to work with the telescope and I really want to be able to figure it out and do this thing and I think personally I would feel failed if I wouldn't be able to at least … put some limit, that gives a good sort of low sensitivity to it [i.e. finding some implications]." (PhD Candidate)

Current state of openness in Astronomy

The effects of current policies affect not only research quality, but also how *FAIR* astronomers' research data and results are. To demonstrate the current state of openness in Astronomy, output can be divided into three categories: *raw data*, *results* and *negative results*. Policies which advocate for openness and good research quality in Astronomy would have to take these as a starting point.

First, *raw*, unprocessed data is the data to be analysed by the researcher. The most prominent example is telescope data. Most telescopes make the raw telescope data public after a proprietary period to the original observer of one year after obtaining through the archives of the observatories. Additionally, researchers can publish their raw or reduced data through the archive of Centre Donnees Stellaire in Strasbourg or various others, once their paper is accepted. On the one hand, this serves the purpose of openness and gives other researchers the possibility to replicate or conduct their own studies. On the other hand, the relative short proprietary period of one year adds to the publication pressure, as only the first to publish receives the credit.

Second, *results* are written up in publications in the form of scientific articles. In a first step of the data analysis, raw data is processed to reduced data through so-called 'pipelines', which are data reduction codes that clean the data from noise and prepare them for the analysis. Sometimes these reduced data are also published in the publically available observatory archives. Results are the final processed data and the conclusions drawn from them. In order to have impact, astronomers publish in journals, but they usually also upload their papers to the open data repository ArXiv. However, *findable* results does not equal *accessible*, even for fellow researchers. The reasons for non-accessibility are for example that reduction codes are mostly not published or that important steps in calculations are not mentioned in the paper, decreasing transparency and hence the paper's communication value. Interviewees urge for more reader-friendly formats, which would enable, for example, expanding sections, interlinking content, adding simulations/ visualisations and publishing code, as it would be possible with modern technology. Despite this, papers are still written in a style inherited from pre-computer times. As information about methods and analysis gets lost with result oriented papers, written in an out-dated manner, it is more difficult to ensure good communication and replicability of research results. In some cases, mistakes even remain undiscovered.

> "The way that papers are currently being written is perhaps too much tied to the way that papers were published in the past. So they were actual papers in a journal, so they had to be sequential. But this is no more the case, now that we have other ways to … read or get information. We can have, not necessarily interactive things, but, at least content that can be separated into different sources. So you can read on one side about the science of the paper, and on the other side about the technical aspects. And currently the two things are merged into a single file, or work. And even if it's true that you intent to have sections like methodologies and results, so if you are not interested in the methodology, or if you actually want to read about the methodology you can go there or not go there. But people will tend to get take [content] away from the methodology section, because they will consider 'Ah, that's too much […], so let's not mention this or put that into an appendix'. So I think there should be the possibility for authors to be very thorough in explaining the methods and even, that includes the possibility to show code. […] In fact in the Astrophysics community, the skills in programming are fairly low in general. Which is worrysome, because I think there are a lot of bugs running around that are not noticed. And because we can't look at the code we can't say, or see whether this is happening or not." (Postdoc 2)

As mentioned above, raw or reduced data is often published along in various archives. However this process is not standardized and often voluntary. While astronomers cite their (data) sources, interviewees criticise that references are not transitive. For example, a literature review might cite the papers it is referring too, but not the data sources that these papers are based on. This seems hardly *fair* for the producers of the data and doesn't add to transparency of the research process. Since there are no incentives for replicability or for transparency in one's research methods, and since publication pressure is high, astronomers do not have the time to consider whether their results are fully *reusable*:

> "And I think that's very bad, when for example, almost the entire results come from a code which is not publically available. So you cannot look at this code and see … if they are actually doing what they say in the paper. And also if they – sometimes they make a mistake. […] So in the sense, the replicability of the work we do … is not always very high. And in the sense that you can download for yourself, in principle all the raw datasets from a telescope and you can redo everything by yourself. So in this sense, yes it's replicable, but never fully replicable." (Postdoc 2)

Third, conducting fundamental research can naturally lead to a dead end, or to *negative results*. The most common examples in Astronomy are non-detections, which are observations that didn't lead to the predicted detection. They are usually only publishable when the researcher can determine their implication or is able to provide upper or lower limits.

> "[Non-detections are not publishable], unless you have a very good [implication], as in for example the way we sort of explained the upper limits with the non-detection. […] The problem is how to tailor it, right? […] So, yeah, unless you have … like a good way, I mean there is some research that published non-detection – for exoplanets sometimes they publish it when they didn't detect it, because sometimes you sort of predict that it should be there […] And it's an anomaly or something like that […] So there are some ways to publish this, but I think it's very … like 10%. There is a whole 90% that doesn't get published and sometimes, like for example, if you just had bad weather, then it's very difficult, right?" (Postdoc 1)

In some sub-fields of Astronomy, non-detections are more common than detections. Most interviewees are convinced that negative results should "absolutely be publishable" (Faculty Member 4). This is because they are seen as valuable with respect to new knowledge about what does not work. As research is the discovery of the unknown, this kind of information is also essential, "because it either can help [the researchers] discount certain theories, or help them kind of support other theories" (Master Student 2). Hence, astronomers are advocating for the exposure of the negative results as well, so that other researchers don't have to 'reinvent the wheel'.

> "I mean when I was at [the famous institution] we said, we should start a journal on non-detections. Because I am really sure that there are people that have been observing the same objects on and on and in without knowing that other people have already done this. Because nobody published when they don't detect anything." (Postdoc 1)

While efforts like this would be welcomed by astronomers, current metrics do not account for non-detections and hence there are little incentives to invest time in the contribution to such 'non-detection journals' if there are no benefits for one's further career in science.

Conclusion & Recommendations

The results of this study show that Astronomy aspires to be open and transparent. However, this requires support from policy makers as current policies do not provide the incentives to invest valuable time in the publication of data and code. Therefore, the observations above imply five recommendations to policy makers when it comes to knowledge utilization and openness:

1. Goodhart's law which states 'when a measure becomes a target, it ceases to be a good measure', always needs to be kept in mind when establishing new policies. In practice this means, that indicators and rewards have constitutive effects on knowledge production, which need to be accounted for.

2. For the afore-mentioned reasons, *FAIR*ness cannot be implemented if there is no incentive for a change in the way research is published. This may require a change in journal templates and paper-writing style to take advantage of the possibilities offered by modern technology. As one of the astronomer's quality criteria are to communicate results well and transparently, papers would be of higher quality if they included more information on in-between-steps; this could be done through expandable sections that a reader could easily skip if wanted. Incentives for including code would lead to a decrease the propagation of errors and increase *replicability*, *accessibility* & *reusability*. If publications provided an interactive way of delivering visible feedback and updating outdated information, *reusability* would benefit and an active exchange within the scientific community would be fostered.

3. Journals could support the astronomers' aspiration for knowledge utilization in terms of pushing knowledge forward by building on previous research. Providing for transitive referencing would make the sources that pieces of research is based on more transparent. 'Open' policies may encourage the journals to do so and the astronomers to use these opportunities.

4. Advocating for openness and knowledge utilization also means valuing knowledge about what doesn't work. Therefore, policies need to reward the publication of research that led to negative results to ensure that researchers who engaged in those studies receive credit for their work, thereby reducing publication pressure. Especially for observational astronomers in sub-fields where the majority of the detections currently are not publishable, 'open' policies provide a hope for improvement.

5. Unlike Astronomy, applied sciences may naturally be more orientated towards finding economic applications for their research. However, this quote applies for all sciences, and is to be kept in mind when it comes to policies for knowledge utilization:

   > "[These politicians] think that they can direct science. […] – *They think they can order discoveries like you order a pizza*. You. Cannot. Order. A. Discovery. […] You have to work on it, you have to try things, you have to experiment. […] But since science is funded mostly by public funding, we are dependent on the strange conceptions that politicians have on how science works." (Faculty Member 3)

Abstract

Existing measures of patent novelty and diffusion mainly rely on patent classification or citations. Given that inventive ideas are embedded in the texts of patents, our study provides a new way to assess novelty and diffusion by text mining techniques. As a validation test, we collect a set of patents linked to famous awards such as the Nobel prize. Overall, text-based measures outperform other commonly-used novelty and diffusion metrics.

Introduction

The increasing number of granted patents echoes the prosperity of innovation activities. Nevertheless, the distribution of patent quality is highly skewed as most innovations are categorized as "incremental" (Nelson and Winter, 1982; Henderson and Clark, 1990). To assess the novelty and diffusion of patents, prior studies mainly rely on patent classification or citation information (e.g. Trajtenberg 1990; Fleming, 2001; Dahlin and Behrens, 2005). The validity of traditional measures have been questioned by recent studies (McNamee, 2013; Arts et al., 2018; Kuhn and Thompson, 2019), and one of the most obvious limitations is that neither patent classification nor citation can mirror the technological content of the patent directly.

In this paper, we focus on the technological contents of patents and develop new patent novelty and diffusion measures by text mining. To do so, we collect US patents granted up to 2018 and identify the first occurrence of new word or new word combination to pinpoint the origin of new technology. The reuse frequency of new words and new word combinations are counted as indicator of technology diffusion. To examine the validity of the new measures, we collect a sample of patents awarded by prestigious prizes, such as Nobel Prize and A.M. Turing Award.

Identifying the Origin and Diffusion of New Technologies

We collect titles, abstracts, and claims of US utility patents granted between 1969 and 2018 from the USPTO, the patent claims research dataset (Marco et al., 2016), and PATSTAT. For each patent, we concatenate the title, abstract, and all claims, lowercase the text, tokenize all words, and remove punctuation, words composed of numbers only, one-digit words, words which appear in only one patent, and stop words. Then, we stem the remaining keywords and remove duplicate stemmed keywords from the same patent. Finally, the technical content of each patent is summarized by a collection of unique keywords.

Based on the processed unique words list, we trace the origin of new technologies by identifying the first patent introducing a given new word or new word combination. All patents are sorted by filing date, and keywords from patents filed before 1980 are used to compile the baseline dictionary (Balsmeier et al., 2018). To assess the diffusion of new technology, we count the number of subsequent US patents reusing the given new word or new word combination. Finally, for each patent, we calculate the total number of new words and new word combinations as indicator of novelty and aggregate reuse frequency of all new words and new word combinations as indicator of diffusion.

We calculate several commonly used novelty and diffusion measures and compare their predictive performance with text-based measures. First, we calculate *new subclass comb* as the number of previously uncombined pairs of patent subclasses and weight it by the total number of subsequent patents reusing the focal new subclass combinations to generate the variable *new subclass comb reuse* (Fleming et al., 2007, Arts & Veugelers, 2014). Similarly, we count the number of previously uncombined pairs of cited patents as *new cit comb* and generate *new cit comb reuse* by aggregating the number of future patents reusing the focal new cited patent pairs (Arts and Fleming, 2018). By examining the diversity of cited and citing patents, we calculate *originality* as one minus the Herfindahl index on classes of citied patents, and *generality* as one minus the Herfindahl index on classes of citing patents (Trajtenberg et al., 1997). Finally, we count *forward cit* as the number of citations received by the focal patent within 10 years (Trajtenberg, 1990).

Validation

To assess the predictive ability of text-based measures, we collect a set of patents with arguably high novelty and diffusion from seven prestigious prizes (Carpenter et al., 1981; Arts et al, 2013), namely Nobel Prize, Lasker Award, A. M. Turing Award, National Inventor Hall of Fame, National Medal of Technology and Innovation, Benjamin Franklin Medal, and Bower Award. Given that most awards (except National Inventors Hall of Fame) do not provide the patent number of awarded inventions, we manually match each awarded invention to US patents by the name of laureate, technical description of the awarded invention, year and laureate's affiliation. For each awarded patent, we select one control patent based on text similarity and approximate filing date (Arts et al., 2018).

First, we run t tests to compare the means of the different measures for the award and control patents. Award patents score significantly higher on all measures, except for *originality* and *new cit comb*. *New word comb reuse* shows the strongest discriminating power. Then we run logit regressions to predict the likelihood of being an award patent. All measures are highly significant except *new cit comb*, and *new word comb reuse* strongly dominates other measures in distinguishing awarded patents from control patents.

Conclusion

We develop new text mining techniques to identify the creation and diffusion of new technologies in the population of U.S patents. Whereas prior studies predominantly rely on patent classification or citations, we focus on technical content of patent to measure the technological novelty and impact of a patent. By a validation test, we show that text-based measures outperform traditional measures. We will provide open access to all code and data for all US utility patents granted before May 2018.

Abstract

Grey literature encompasses a range of relatively informal textual outputs that are not indexed in citation databases. Although they are usually ignored in research evaluations, it is important to develop methods to assess their impact so that their contributions can be recognised, and successful types of grey literature can be encouraged. This article investigates the extent to which 97,150 UK government publications were cited by Scopus articles and Google Books during 2013-2017 in eleven broad subject areas. A method was used to semi-automatically extract citations to the UK government publications from articles and books with high recall and precision. The results showed that Scopus citations are more common than Google Books citations to UK government publications, especially for older documents, and for those in Healthcare, Education and Science. Since the difference is not huge, both may provide useful grey literature impact data.

Introduction

'Grey Literature' or 'Gray Literature' is a term which describes textual documents that are not published in a standard academic format, such as a book or journal article. The term includes reports, regulations, and policy documents, which are important outputs from many governments and organisations. Fuzzy for many years and still not concrete due to the boundaries between grey literature and non-grey literature varying depending on the situation (IGLWG 1995), the Prague definition of 2010 seems to be now accepted: "*Grey literature stands for manifold document types produced on all levels of government, academics, business and industry in print and electronic formats that are protected by intellectual property rights, of sufficient quality to be collected and preserved by library holdings or institutional repositories, but not controlled by commercial publishers i.e., where publishing is not the primary activity of the producing body*" (Schöpfel, 2010, p.11). The US Interagency Gray Literature Working Group has given the following alternative definition: "*Foreign or domestic open source material that usually is available through specialized channels and may not enter normal channels or systems of publication, distribution, bibliographic control, or acquisition by booksellers or subscription agents*" (IGLWG, 1995). Hence, grey literature publications can include, but are not limited to, unpublished research, governmental reports, policy statements conference proceedings, and theses or dissertations (GreyNet, 2019, UNE, 2019).

There are many high-profile grey literature repositories, confirming that this is an important document type. The UK government publication repository includes almost 120,000 annual reports, regulations, statistics, or policy documents in different topics (https://www.gov.uk/government/publications). This is a specialised source of grey literature in government policy making. The repository hosts many policy-making papers, such as healthcare reports, which are of high value to society and can be used to improve information on risk factors and how healthcare research is used (Institute of Medicine, 2009).

Other grey literature repositories include those of the World Health Organization (WHO, https://www.who.int/publications/en/), the United Nations (https://digitallibrary.un.org) and the World Bank (http://www.worldbank.org/en/research/brief/publications). Given that large amounts of grey literature have been created by governments and other important organisations, it would be useful to know if they have an impact so that their creators can decide which types of document are worth producing. This article focuses the academic impact as a first step towards this goal.

Citation analysis is commonly used to assess scientific impact of published research. However, there seems to be no practical or standard method to identify grey literature citations. Grey literature publications do not have well-established, centralised and standardised sources, and hence impact indicators are more difficult to calculate.

Google Scholar has been suggested as a good source for monitoring the impact of grey literature (Orduna-Malea, Martín-Martín & López-Cózar, 2017) and dissertations (Kousha & Thelwall, submitted). However, Google Scholar queries cannot be automated on a large scale, except for the facilities of Publish or Perish (Harzing, 2010) and it is therefore not suitable for large scale grey literature evaluations. Web queries have also been proposed for small sets of documents (Wilkinson, Sud, & Thelwall, 2014), but these do not necessarily reflect academic impact.

Given the lack of an accepted solution for determining the academic impact of grey literature, this article proposes and demonstrates two new approaches. First, Scopus (API) cited reference searches can be used to find citations to non-standard academic outputs (Kousha, Thelwall, & Rezaie, 2011) and complex queries can be designed to identify citations to large numbers of documents. Second, the Google Books API can also be used to automatically identify citations to monographs with high accuracy (Kousha & Thelwall, 2015). These strategies are proposed and are important to determine if feasible for grey literature. This paper describes the two new methods in detail and compares their results for 97,150 UK government publications from 2013-2017 across eleven broad subject areas.

Research questions

The underlying goal is to assess if Scopus and Google Books citation searches can be automated for capturing citations to grey literature publications. UK government publications are the focus of the study because the UK government publishes a large number free online, its repository can be crawled, and the authors are familiar with the UK context.

1. Can academic citations to grey literature publications be automatically extracted from Scopus and Google Books on a large scale?
2. Which citation search strategy or indicator is most useful for the impact assessment of UK government publications?
3. Are there disciplinary differences in the answer to the above question?

Methodology

This section describes how the new method was developed through small scale pilot studies.

Data sets

The online repository of documents released by the UK government (held at https://www.gov.uk/government/publications, hereafter: 'the repository') is classified by government-defined policy area and year of release (see Table 3 in the online Appendix (https://figshare.com/s/51a8308bdf43772820b3). This data was collected in July 2018 by a bespoke crawl routine added to the free Webometric Analyst (lexiurl.wlv.ac.uk) software. Each policy area was combined into more general topic areas (Table 1). The most recent five years were chosen to be most relevant for use in this method due to the increase in uploads to the repository at that time. Out of 137,559 documents available, 97,150 (70.6%) are from the years 2013-2017. Each document has a unique URL as well as a title. The URLs were used in subsequent searches to identify citations.

Table 1. All 11 grey literature areas used by combining policy areas as defined in the repository, split by years used, along with total over 2013-2017 (grey and policy areas sorted by largest size).

Grey literature area	*Policy areas merged*	*2013-2017*	*2013*	*2014*	*2015*	*2016*	*2017*
Economics	Business and enterprise; UK economy; Tax and revenue; Employment; Trade and investment; Financial services	21112	2346	5373	4287	4155	4951
Government	Government efficiency, transparency and accountability; Local government; Government spending; Regulation reform; Media and communications	11399	1618	2987	2343	2005	2446
Environment	Environment; Food and farming; Climate change; Wildlife and animal welfare; Rural and countryside	10997	1591	2557	2378	2175	2296
Security	Crime and policing; Law and the justice system; Defence and armed forces; Public safety and emergencies; National security	9729	1096	2308	2030	2028	2267
Housing and travel	Transport; Housing; Planning and building	8995	1281	2028	1766	1574	2346
Healthcare	National Health Service; Public health; Social care	8836	892	1535	1910	2156	2343
International affairs	Borders and immigration; Foreign affairs; International aid and development; Wales; Northern Ireland; Scotland; Europe	8376	1129	1494	2115	1759	1879

Total		97150	12338	22049	20787	19664	22312

Scopus API citation searches

To find citations to one or more URLs from documents indexed by Scopus, a query of the following form can be used in either the Advanced Search interface or submitted to the Scopus API:

REF("[*search term*]") OR REF("[*search term*]") OR REF("[*search term*]")…

The result is a set of journal articles, magazines, conference papers or books indexed by Scopus that contain a citation in their reference section that matches any [*search term*]. Grey literature titles were not effective as search terms because they were often too short. For example, the UK government report, "Ahead of the curve" has a subtitle of "How UK motorsport technology and innovation can benefit your company". Due to the subtitle not being part of the title, almost exclusively false matches were found in Scopus (1288) when using the article title as the [*search term*]. In comparison, only one match was found when using the URL and omitting https://www., here, REF("gov.uk/government/publications/ahead-of-the-curve"), and this was a correct match. This strategy was not perfect because some URLs can be contained within longer URLs and documents could be cited by title without an URL. Nevertheless, the method can identify citations with high precision. These queries were submitted via the Scopus API to automatically gather the results.

For Scopus API to search the database, a text file for each grey literature area in each year was created. The file contained each query term, listed one per line. Each query included the "REF" part as above, as it is still required to search only the reference sections within Scopus. To match Google Books searches (discussed below), queries without the leading part (www.gov.uk/government/) were used. An example of such a query, using the example above, is:

REF("publications/ahead-of-the-curve")

The list of queries was then input into Scopus API search which automates the search process. In total, 235 query files were produced (47 policy areas per year across 5 years). Results returned are files of all query matches found. After some cleaning and matching, results files were combined into grey literature areas per year (Table 1). The number of matches per policy and grey literature area, and per year can then be calculated, and hence, impact assessed.

Google Books API citation searches

Google Books indexes a substantial fraction of the world's books. The academic books in its collection may contain references to grey literature. The free Google Books API can be queried via Webometric Analyst (WA) for URLs, as in the case of Scopus above. Whilst Scopus only returns a result if an exact match is found within the reference section, Google Books also returns close matches but highlights the matched section in the results returned. WA contains routines to filter out false positives by excluding results that do not contain the original query URL. However, due to the length of the original query on some URLs and imperfections in the Google Books description field (such as additional spaces or text wrapping issues), matches can be missed. Due to this, a second matching method was also used, as described below. All URLs have the form:

gov.uk/government/[*article-title-separated-by-hyphens*]

Here, "gov.uk" is the hostname and "government/[*article-title-separated-by-hyphens*]" is the path. The hostname and first part of the path (gov.uk/government/) are common to all grey literature references within this repository and are therefore useful to match true citations. Nevertheless, text wrapping could cause a problem due to the length of some URLs. If the URL part of the reference were to wrap to more than one line, URLs referenced might change due to the addition of an extra hyphen or a line break, causing a match to be missed. To avoid this issue the hostname and first part of the path (gov.uk/government/) were removed and two Google Books search strategies were formed.

For Google Books API to search the database, a text file for each grey literature area in each year was created. The file contained each query term, listed one per line. Here, each query did not include the "REF" part (as in Scopus), as Google Books does not have the ability to search a reference section specifically. Examples of each search strategy for the example above, to find matches for the document at URL gov.uk/government/publications/ahead-of-the-curve, are:

publications/ahead-of-the-curve
www.gov.uk

The list of queries for each search strategy was then separately input into Google Books API search contained within Webometric Analyst which automates the search process. As before, 235 query files were produced per search strategy (47 policy areas per year across 5 years). Results returned are files of all query matches found, including false positives where a similar match is found. Webometric Analyst also includes further routines to match the original query to the description output for each result, to ascertain true matches.

In pilot studies, comparisons between the two Google Books search strategies were performed to determine if one is inherently more suitable than the other. It was decided that the second search strategy using only the hostname (queries matching only www.gov.uk) was too general, causing matches to general webpages on the UK government website. The first search strategy, although possibly missing some matches due to the length of each query, was more specific and has better precision than the other search strategy.

From this decision, the Scopus search strategy defined above was finalised to be the same as Google Books – so both Scopus and Google Books were searched with the same part of the URL per query. This should help equate precision levels across the separate digital library searches.

After some further cleaning and matching, results files were combined into grey literature areas per year (Table 1). The number of matches per policy and grey literature area, and per year can then be calculated, and hence, impact assessed and compared to Scopus.

Following some pilot studies, some of the highest-ranked documents have very generic URLs. These may be overrepresented in this study as the citation count for the URL may include other URLs within the repository that start with exactly this URL, followed by further phrases.

Manual checking of results is needed, so precision was also calculated due to help remove the inclusion of false positives, estimated from a sample. A random sample of 50 documents in the original data that had at least one citation in Scopus API was extracted and manually searched in Scopus Advanced Search. This was then repeated for a further random sample of 50 with at least one citation in Google Books API and checked manually in Google Books. Precision for each document was calculated by comparing the automated citation count and manual citation count, and the smaller of the two was divided by the larger. The overall precision of each online library was then estimated by taking the geometric mean of the 50 document's precision levels.

Results

Proportions of UK government publications with Scopus or Google Books citations

Since most documents received no citations, the results focus on the proportion cited rather than the average number of citations per document. Other measures of impact exist that can deal with mostly uncited datasets, such as (Equalised) Mean-based Normalised Proportion Cited (MNPC and EMNPC) or Mean Normalised Log-transformed Citation Score (MNLCS) but require a comparison to a world average (Thelwall, 2017). Here, comparisons are between different online libraries across different disciplines, not compared to similar non-grey literature articles.

The results are split by year because comparing the proportion cited between years may be misleading due to the different lengths of time for a document to be cited; older documents with lower impact may report higher than newer document with a higher potential impact.

Comparisons between the original 47 policy areas as defined in the repository between the two search strategies are in the online Appendix (Table 3: https://figshare.com/s/51a8308bdf43772820b3).

The proportion cited from Scopus article path matching are always significantly above the proportion cited from Google Books with article path matching (all lower 95% confidence intervals for Scopus are larger than upper 95% confidence intervals for Google Books article path), across all years and all grey literature areas (55 occasions, 11 areas per year across 5 years) (Figures 1-5).

The more impactful grey literature areas have a proportion cited on Scopus >10% for most years, and some lesser impactful areas still have a proportion cited on Scopus >5% for older years, so a substantial minority have been cited.

As can be seen in figures 1-5, the proportion cited is generally higher in Scopus, and it seems that journals may cite grey literature more often than books. Nevertheless, the difference may be due to different levels of recall for the two search strategies.

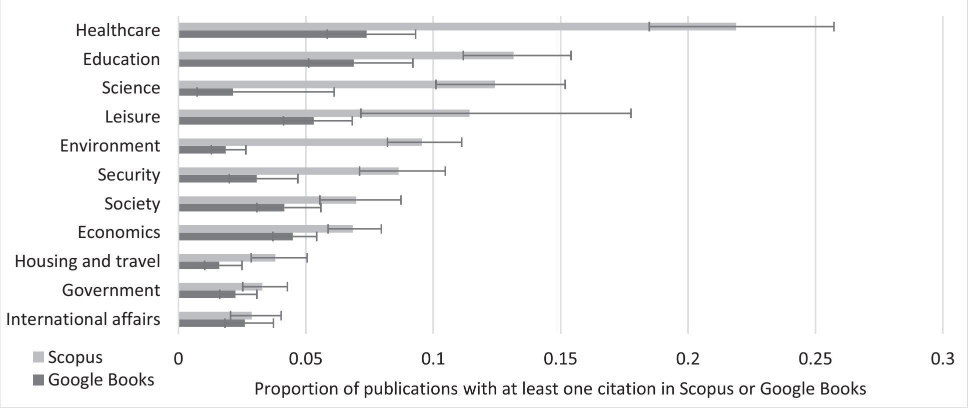

Figure 1. Proportion of UK government publications in 2013 with at least one citation in Scopus or Google Books with 95% confidence interval across 11 areas (Sorted by largest Scopus cited).

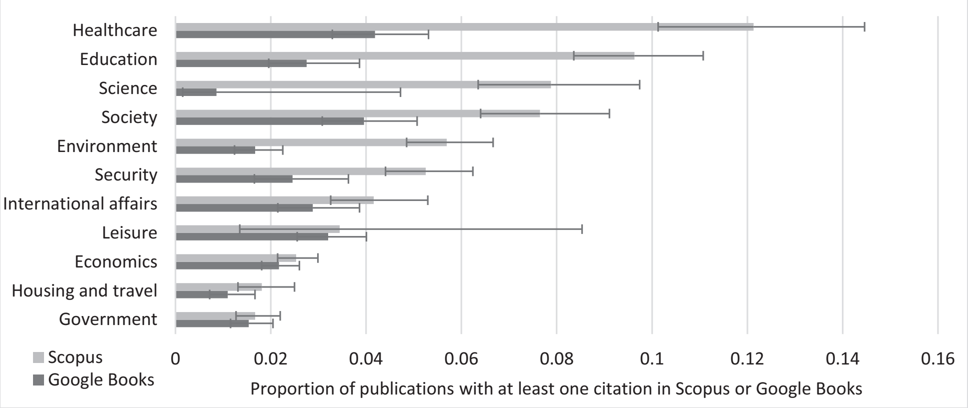

Figure 2. Proportion of UK government publications in 2014 with at least one citation in Scopus or Google Books with 95% confidence interval across 11 areas (Sorted by largest Scopus cited).

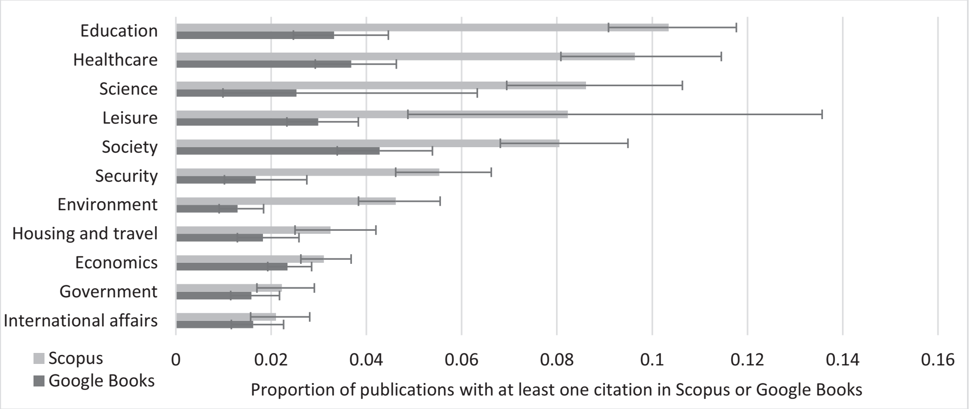

Figure 3. Proportion of UK government publications in 2015 with at least one citation in Scopus or Google Books with 95% confidence interval across 11 areas (Sorted by largest Scopus cited).

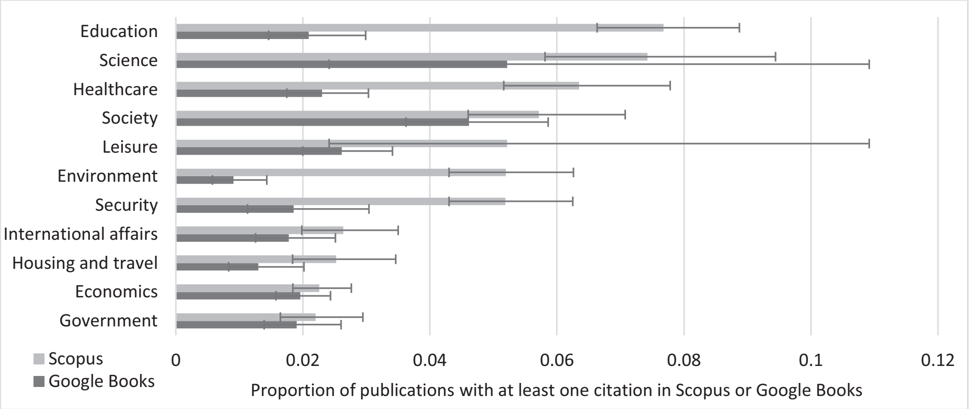

Figure 4. Proportion of UK government publications in 2016 with at least one citation in Scopus or Google Books with 95% confidence interval across 11 areas (Sorted by largest Scopus cited).

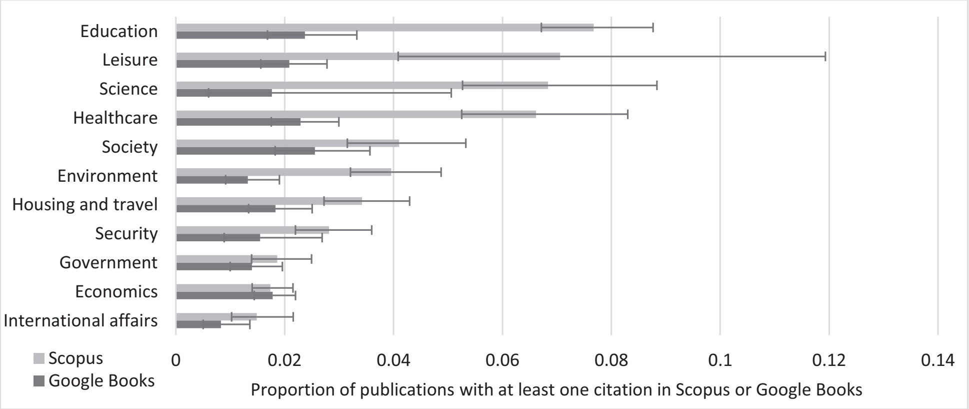

Figure 5. Proportion of UK government publications in 2017 with at least one citation in Scopus or Google Books with 95% confidence interval across 11 areas (Sorted by largest Scopus cited).

Characteristics of the most cited UK government grey literature in Scopus

The top three grey literature areas by proportion cited are Healthcare, Education and Science for each of the years 2013-2016 within Scopus references, and the same three are in the top four in 2017, with Leisure as second most cited, although with a large confidence interval.

In the first two years, Healthcare had the most impact, and has the second, third and fourth highest for 2015-2017 respectively. Education is in the top 2 most impactful grey literature areas; highest in 2013 and 2014, and second in all other years. Science is always third most impactful except for 2016, when it was second. In contrast, the grey literature areas International affairs, Economics and Government regularly finished bottom or near-bottom of the most impactful topics.

The grey literature area Healthcare in 2013 appears to be an anomaly due to its relatively high proportion cited (Scopus 0.22), with no other Scopus measurement above 0.13 for any year. A specific event, such as a national news story or major change in guidelines, may have caused a relative increase in 2013 research citing grey literature.

Table 2 shows the 25 most Scopus-cited grey literature documents across all subject areas. The five most cited grey literature documents in each subject area are shown in the online Appendix (Table 4: https://figshare.com/s/51a8308bdf43772820b3).

Table 2. Top 25 most cited UK government publications as found by Scopus.

Title (in bold) *URL (preceded by gov.uk/government/)*	*Year*	*Policy area*	*Grey literature area*	*Scopus citations*
Prisoners' criminal backgrounds and proven re-offending after release publications/2012	2013	Crime and policing	Security	3933
Housing publications/housing	2016	Tax and revenue	Economics	472
Climate change publications/climate-change	2017	Environment; Food and farming; Wildlife and animal welfare	Environment	333
Costs in disputed applications (PG38) publications/costs	2017	Housing; Business and enterprise	Housing and travel; Economics	260
Mental health and travelling abroad publications/mental-health	2014	Foreign affairs	International affairs	224
Bridges publications/bridges	2015	Government efficiency, transparency and accountability	Government	129
English indices of deprivation 2015 statistics/english-indices-of-deprivation-2015	2015	Community and society	Citizenship	121
Sustainability publications/sustainability	2013	Tax and revenue	Economics	112
NHS reference costs 2012 to 2013 publications/nhs-reference-costs-2012-to-2013	2015	National Health Service	Healthcare	97

NHS reference costs 2014 to 2015 publications/nhs-reference-costs-2014-to-2015	2015	National Health Service	Healthcare	84
NHS reference costs 2013 to 2014 publications/nhs-reference-costs-2013-to-2014	2015	National Health Service	Healthcare	83
Staffing publications/staffing	2017	Government efficiency, transparency and accountability	Government	72
NHS Constitution for England publications/the-nhs-constitution-for-england	2015	National Health Service	Healthcare	65
E-cigarettes: an evidence update publications/e-cigarettes-an-evidence-update	2015	Public health	Healthcare	56
Start active, stay active: report on physical activity in the UK publications/start-active-stay-active-a-report-on-physical-activity-from-the-four-home-countries-chief-medical-officers	2016	National Health Service; Public health	Healthcare	54
Energy consumption in the UK statistics/energy-consumption-in-the-uk	2017	Energy; Climate change	Science; Environment	50
NDNS: results from Years 1 to 4 (combined) statistics/national-diet-and-nutrition-survey-results-from-years-1-to-4-combined-of-the-rolling-programme-for-2008-and-2009-to-2011-and-2012	2017	National Health Service; Public health; Children and young people	Healthcare; Citizenship	46
Facts and figures statistics/facts-and-figures	2014	Business and enterprise	Economics	45
Social media publications/social-media	2015	Wales	International affairs	44
Websites publications/websites	2014	Transport; UK economy	Housing and travel; Economics	44
Open Data Charter publications/open-data-charter	2013	Government efficiency, transparency and accountability	Government	42

The top-ranked documents have generic URLs, such as gov.uk/government/publications/2012 (first in Table 2) and are overrepresented here as this URL does not represent the entire article title, and there are other URLs within the repository that start with this URL (gov.uk/government/publications/2012-user-event-taking-part-survey for example). Following this, URLs such as gov.uk/government/publications/open-data-charter (25th in Table 2) appear to be a generic URL due to words used and length, but will not be as generic as the first one.
For example, documents with citation counts that matched between Scopus API and Scopus Advanced Search had an accuracy of 1 (100%). Those with citation counts of one in either

method and two in the other had an accuracy of 0.5 (50%), and vice versa. This way, each non-agreement results in a fall in accuracy, whether the non-agreement is due to a false positive or a missed match. A combined precision of 0.82 (82%) was estimated for Scopus and 0.71 (71%) for Google Books, each calculated using the geometric mean of 50 text's precision levels.

Excluding these general URLs (Table 2), the themes of the most cited articles (articles with >60 citations) are statistics of an annual report, multiple annual healthcare reports, general healthcare updates/studies and the NHS Constitution. This agrees with the results at the start of this section, showing that healthcare is generally the most cited topic within grey literature. This is possibly due to the importance that current healthcare policy has on relevant practice from medical professionals, teaching within the sector and future policy changes in a publicly transparent field. Furthermore, an example such as "E-cigarettes: an evidence update" is one of the most cited, non-generic URL documents. It is of note due to the rising amount of healthcare research now surrounding the use of electronic cigarettes and derivatives, due to the unknown long-term problems with their use (Callahan-Lyon, 2014).

Another example of time-appropriate research is that of the document "Start active, stay active: report on physical activity in the UK". It has a very specific URL but is relatively highly cited. Physical activity is a useful tool for combatting many issues such as obesity (Bray et al, 2016) and cardiovascular disease (Wilson, Ellison & Cable, 2016), and with an increase of these problems in recent years, it is important to make sure research incorporates all aspects of research, including that of grey literature.

As shown in the online Appendix (Table 4: https://figshare.com/s/51a8308bdf43772820b3), and ignoring the generic URLs cited (as in Table 2), the types of publication within each grey literature area appear to vary. For example, like Healthcare as mentioned in the analysis of Table 2, the grey literature areas Housing and Travel, Science and Security all have highly cited annual reports that would naturally be updated yearly. These may be highly cited as they are updated each year, so the most recent version is always relevant. As new versions are released, old forms may be cited for comparative reasons.

Education, for example, features highly cited articles that centre around unique-to-the-field reasons, namely the National Curriculum. Four of the top five most cited articles are focussed on different subjects or levels within the curriculum, across all ages from school entry to leaving at age 16 or 18. Education is arguably one of the most important areas of research due to the importance of learning from a young age, in addition to the increasing adoption of technology in the classroom at all levels in recent years (Davison & Lazaros, 2015, Domingo & Garganté, 2016). Alongside this, a highly cited article on SEND (Special Educational Needs and Disabilities) is about codes of practice within this area (also classified as a Society grey literature document in this study). This may be due to an increasing focus on inclusion of children with special education needs in the classroom within the regular school lesson (Hornby, 2015, Bryant, Bryant & Smith, 2017).

Discussions and limitations

Using Google Books and matching just the term www.gov.uk in the description field gives more results due to the inclusion of extra spaces and line breaks in the description. However, this is not a good strategy because it introduces extra false matches. Any mention of any governmental page within the description field will cause a match due to all pages starting with the hostname, even if the match is a non-article such as a general webpage. Following, it can be suggested that Google Books article path has a higher precision but likely will miss some matches. Scopus appears to have a balance in terms of higher recall and improved precision compared to Google Books search strategies – a more specific matching term with no major issues found when matching article path to generate results.

From this, Google Books article path has been shown to display a lower proportion cited overall. Although no 'gold standard' to measure online impact within grey literature exists, the results suggest that Scopus API references when matched with the article path part of the URL is likely the best search strategy from those studied here.

To ease the collection and impact assessment of grey literature in future, it may be useful for publishers of these documents to provide their publications with persistent identifiers like DOI.

Limitations

The results are limited using a single case study (UK government publications). The Scopus API requires a paid subscription to use and is limited to 10,000 queries per week. Research of this size may take 10 weeks (n=97,150 for this study), and larger studies may take longer.

Merging of UK government policy areas are somewhat arbitrary for certain areas. Although the policy areas 'schools', 'further education and skills' and 'higher education' form a logical group, others are less intuitive, such as 'food and farming' within 'environment' and the 'housing and travel' grouping. It appears that the more ambiguous groupings were the less impactful, so should not affect the results much, but care should be taken if grouping into grey literature areas. In addition to this, the policy areas defined in the repository used have changed since data was gathered for this study, reducing the number of policy areas. As the total is reduced, it is likely that this may counter some of the problems when defining grouping into grey literature areas.

Several generic URLs were found within the repository that produced many incorrect search matches. This problem needs to be mitigated by data cleaning. The removal of generic URLs may be necessary if studying characteristics of specific documents. Determining which URLs are generic and specific requires manual checking of results, which increases time needed. For the results with extreme citation counts (publications/2012 with 3922 citations, for example), a sample of these matches must be checked to assess the proportion (accuracy and coverage) of false matches to generate an estimate of the total number of correct matches.

Conclusions

In answer to the research questions, a semi-automatic method can be used to identify grey literature publications for both Scopus and Google Books. Although some data collected may need to be cleaned and some text editing required for matching in Webometric Analyst, most steps of the method can be run automatically. From this, the impact of a grey literature article can be gauged using a specific repository. If the repository can be crawled or data can be manually gathered, Scopus can be used to determine how often it has been cited. In addition, the impact of grey literature documents can also be assessed through Google Books.

Scopus appears to be a better measure of impact for grey literature compared to Google Books, at least in terms of generating more matches in addition to a higher level of precision (generated from a random sample of 50 cited documents). Pilot studies showed a larger impact measurement if matching Google Books to a more generic but still suitable matching term. Although recall will be higher, precision would be lost due to the matching term not including any part of the article title (or URL equivalent). Precision and recall are acceptable when using this method for grey literature, as judged for Scopus API, showing clear differences in impact for each grey literature area across all years, when it exists. Google Books suffers with precision if the matching term is too generic, and recall is lower with equivalent matching terms.

Finally, Healthcare, Education and Science seem to be the most cited type of grey literature, at least in terms of UK government documents. Researchers assessing document-based knowledge flows in these areas should include grey literature within their analysis in order to get a more complete picture, who can be assisted by publishers of grey literature by including persistent document identifiers such as DOI.

Appendices

Appendix 1 (Table 3), Appendix 2 (Table 4), and Appendices 3-7 (Figures 6-10), as referred to above, can be found in the online Appendices (https://figshare.com/s/51a8308bdf43772820b3).

Abstract

Scientific research has been acknowledged as an important knowledge resource for developing technologies. Studying science-technology linkages is crucial to help understand the mechanisms of innovation. Using nanotechnology as a case study, this paper investigates what types of scientific research can help improve the impact of technologies. This study uses backward and forward citation analysis, extracted from the Derwent World Patents Index (DWPI). Non-patent citations (NPCs) from each patent are further connected with records indexed in Web of Science, and the forward citations for the cited articles are collected. On the one hand, our results confirm that there is an important contribution from science to technology. High-impact academic research has significantly contributed to the development of high-impact patents. On the other hand, this study also reveals the heterogeneous pattern of patents citing scientific publications, depending on the organizational type, country, and knowledge origin. Compared to those in the U.S., patents developed by Chinese inventors tend to reply on more recent science but with a narrower scientific scope.

Introduction

Over the past decades, the degree to which scientific publications have supported the development of industrial innovations has increased remarkably (Narin et al. 1997; Wang and Li 2018; Branstetter 2005). The involvement of science in technology has not only helped spur new innovations (Mansfield 1991; Beise and Stahl 1999) but also helped to improve the quality of inventions (Sorenson and Fleming 2004; Wang and Li 2018; Branstetter 2005). Despite the rising science and technology (S&T) interactions and the important role science has played in accelerating technologies, as pointed out by many scholars (Meyer-Krahmer and Schmoch 1998; Acosta and Coronado 2003), the mechanisms of S&T linkages are still to a large extent unknown. This is partly due to differences in technological complexity across regions or sectors, and the difficulty of measuring the linkages between science and technology (Mansfield 1991; McMillan et al. 2000; Narin et al. 1997; Acosta and Coronado 2003).

In the science-based fields, such as biotechnology and nanotechnology, it is believed that “academic science might yield the highest economic reward” (Meyer-Krahmer and Schmoch 1998), but yet the communication is insufficient and a better understanding of S&T interactions is crucial. Given the well-recognized sector-specific nature between science and technology, this study focuses on one technological domain, i.e. nanotechnology.

The contributions of this paper are two-fold. On the one hand, we explore how science has contributed to the quality (or impact) of nanotechnologies. On the other hand, special attention is paid to the heterogeneous nature of S&T interactions, depending on the organizational types, countries, and knowledge origins.

Theoretical framework and research questions

The contribution of science to technology can be influenced by various factors, such as the characteristics of the national systems of innovation (Meyer-Krahmer and Schmoch 1998), and the level of technological complexity in a region (Acosta and Coronado 2003). If inventors preferentially cite papers authored in their own country, as suggested by Narin et al. (1997), the pattern of S&T linkages would also depend upon the availability of local scientific knowledge resource. In this study, we aim to link up the characteristics of science with the quality (or impact) of technologies. That is, to explore what types of scientific knowledge are more beneficial to help improve the patent quality (or impact). We focus on a series of scientific characteristics, including quality, newness, scope and country of origin of scientific research.

Quality of science

In the existing literature, the quality of academic research is mainly represented by the evaluation indicators (i.e. ranking) of research departments. However, whether research from higher-quality research departments is really more beneficial to technological development is still a matter of debate. On the one hand, some scholars suggest that the contribution of science to industrial innovation is directly related to the quality (ranking) of the research departments where scientific research has been conducted (Mansfield 1995). It is believed that more reputable research institutes are more likely to produce research that industry is looking for (Tornquist and Kallsen 1994). On the other hand, studies also show that the quality of a research department has no impact on the probability of S&T interactions. Although the ranking of a research department is associated with the percentage of citations received by this institute (Mansfield 1995; Mansfield and Lee 1996), we argue that it is the quality of cited articles, rather than the quality of research institutes, contributing to the technological development. Hence, in this study we move a step further to investigate individual articles cited by patents. The cited articles are linked with information from Web of Science. We use the number of forward citations received by these articles as a proxy for the quality of cited science. By linking up the quality of cited publications with the quality of citing patents, we aim to test whether highly cited articles would help increase the impact (proxied by forward citations) of a citing patent.

Age of scientific results

Recent scientific publications represent the results of up-to-date academic research. However, it takes time for inventors to recognize and utilize scientific results, i.e. there is usually a time lag between the appearance of research output and its application to industry (Adams 1990;

Mansfield 1991). Earlier studies attempted to test the time lag between patents and the cited academic articles. Popp (2017) finds that the probability of patents citing articles peaks 15 years after the article was published, while Finardi (2011) suggests that the time lag between production of scientific knowledge and its technological exploitation is about 3-4 years. As explained by Popp (2017), the time difference is likely caused by the sector-specific feature, for instance, energy research may take longer to progress to a commercialized product. Besides the sector-specific feature, our study takes country-specificity and difference of knowledge origin into consideration. By controlling the country, organization, and knowledge origin variables, we expect that a timely knowledge transfer from science to technology is valuable for generating high-impact technologies.

Scope and variety of knowledge

In addition to the feature of scientific quality mentioned above, the quantity of cited articles is also one of the factors influencing the effect of knowledge transfers from science to technology. With the increasing trend of scientific application into technological development (Narin et al. 1997; Wang and Li 2018; Branstetter 2005), one may wonder whether more references to scientific articles would lead to a better quality patent. What's more, it has been believed that the diversity of knowledge is an important factor facilitating knowledge creation (Liao and Phan 2016). However, by looking at how science and technology are combined in one specific field, Appio et al. (2017) suggest that a high degree of knowledge diversity does not always lead to more impactful inventions. We contend that the patterns of citation (in terms of how many scientific articles to cite or what kind of scientific articles to cite) are country-specific. In studying knowledge transfer, it is important to note the differences between countries of origin (Fernández-Ribas and Shapira 2009).

Knowledge origins

Knowledge resources can be explored by studying the country of origin of references cited by industrial patents. Knowledge documented in an article is known as codified knowledge that can be easily circulated and exchanged. Different from tacit knowledge which is often socially localised, codified knowledge can be transferred easily over large distances (Cohendet and Meyer-Krahmer 2001). In theory, there is an equal chance for inventors to access and cite codified knowledge (e.g. scientific articles) from various geographical locations. However, studies also find that each country's inventions preferentially cite scientific articles from their own country (Narin et al. 1997), or even preferably from closely located institutes (Beise and Stahl, 1999). This indicates that, to some extent, knowledge from home-country might be more relevant than that from foreign countries.

We tend to agree that there is a national bias in the citation patterns for industrial patents (Narin et al. 1997; McMillan et al. 2000). Although the existing studies have been limited to the developed countries, such as the U.S. and Japan, we investigate whether there is also a national bias in the citing patterns in developing countries.

Data collection and methodology

Disciplinary origin is an important factor in influencing the pattern and intensity of knowledge transfer from science to technology (Wang and Li 2018; McMillan et al. 2000). Scientific research may play a more important role in stimulating more complex technologies, while for less complex technologies, scientific elements may not be crucial. In this study we focus on the field of nanotechnology, which is of one the promising and key enabling technologies important for both developed and developing regions (Heinze 2004; Wang et al. 2013; Wang et al. 2019; Coccia and Wang 2015).

The patent data used in this study are collected from the Derwent World Patents Index (DWPI) via the platform Derwent Innovation (previously known as Thomson Innovation). Since 2011, all patent offices worldwide have classified nanotechnology uniformly under the International Patent Classification (IPC) system. The old Y01N system has been transformed to the B82Y category[1]. In the new system, all nanotechnology related patents are classified with an IPC code B82[2]. In total there are 129,123 patent applications related to nanotechnology in the studied period of 2000-2015. For each patent, both backward citations and forward citations are collected. Backward citations include both patent citations and non-patent citations (NPCs). After removing those nano patents without non-patent citations, we obtain 66,105 patents citing non-patent documents. NPCs consist of various types of references, including scientific articles, withdrawn patents, technical manuals, databases, web-based information, news, etc. This study aims to investigate the patents citing scientific articles published in Web of Science (WoS) indexed journals. Based on the DOI and title of the listed non-patent citations in each patent, we identify whether these NPCs are indexed by WoS journals. If they are not, we remove the patents from our sample. This step results in 33,050 nano patents[3].

Based on the information of assignees, the above patents are classified into three organizational types: 1) patents developed by firms, 2) patents developed by research institutes and universities[4], and 3) firm –university collaborated patents. Country codes are extracted based on the addresses of inventors. For each patent, we collect its publication ID, application date, backward citations

[1] http://www.epo.org/news-issues/issues/classification/nanotechnology.html.

[2] There are two sub-categories covered, i.e. B82B and B82Y. The former refers to inventions related to nano-structures formed by manipulations of individual atoms, molecules, or limited collections of atoms or molecules as discrete units; manufacture of treatment thereof. The latter refers to inventions related to specific uses or applications of nano-structures; measurement of analysis of nanostructures; manufacture of treatment of nano-structures (see more at http://www.wipo.int/ipc/itos4ipc/ITSupport_and_download_area/20130101/pdf/scheme/full_ipc/en/b82.pdf).

[3] Scientific references (added by examiners) with a publication year later than the patent publication year are removed.

[4] This type of patent is also called university patents in this paper.

(including number of cited patents and number of cited WoS publications), number of forward citations, and assignee countries. For the cited WoS publications, we collect the information on publication year, ut number[5], number of forward citations, countries of authors.This study aims to explore the impact of scientific research on the quality of technologies. Patent forward citations are collected to represent the impact or quality of the investigated technology. For each nano patent, we construct the following indicators.

Scope of technological background is represented by the number of cited patents (nr_cited_patents), $\sum P_i$. If a great number of patents have been cited by one new invention, this indicates that this new invention was developed based on a wide range of technologies. Otherwise, the scope of technological background is regarded as narrow.

Scope of scientific background is denoted by the number of cited WoS articles (nr_cited_pubs), $\sum S_i$. Similar to the previous indicator, citing more scientific publications indicates a wider scope of scientific background.

Newness of cited scientific articles is measured by the average publication year of the cited WoS articles. Suppose one nano patent cited N WoS scientific articles and the publication year of each article is expressed as YS_i, then the value of newness of cited scientific articles can be calculated by $\frac{\sum_{i=1}^{N} YS_i}{N}$. A lower newness value indicates that this group of cited scientific articles is on average relatively old, while a higher newness value indicates that this patent has been developed based on a group of more recent scientific articles.

If one nano patent cited N WoS scientific articles and the forward citation of each article is FCS_i, then the average forward citation of this group of scientific articles can be measured by $\frac{\sum_{i=1}^{N} FCS_i}{N}$. A higher level of average forward citation implies that a group of high-quality scientific research has been used in developing this studied nano patent. A lower level of average citation implies that this nano patent has been developed based on less impactful (or relatively unknown) scientific articles.

Variety of scientific knowledge resources is measured by the number of author countries of the cited scientific articles. Duplicates have been removed from the list of countries. For instance, if a nano patent cites three WoS articles and the author countries for these three articles are U.S., Netherlands, and U.S., respectively, the value of 'variety of scientific knowledge resources' for this patent is counted as two[6].

[5] This is the accession number, a unique identifying number associated with each record indexed in Web of Science.
[6] The country name of U.S. is counted once.

We use cited WoS articles from the U.S. to represent knowledge flows from advance countries, and cited WoS articles from China to represent knowledge flows from emerging economies. Given that the nature of patents developed by industry is different from that of patents developed by universities (Henderson et al. 1998), we separate firm patents from university patents in most models. Poisson and Negative Binomial are two types of regression used often to model count data. In our case, due to the over-dispersion feature of the outcome variable (i.e. the variance with each sub-group is higher than the mean within each sub-group), we use Negative Binomial regressions.

Results and discussion

Considering the fact that the invention pattern of firms is different from that of research institutes or universities (Wang and Li, 2018), we provide a separate analysis of patents from different organizational types. The scope of technological background (i.e. number of cited patents) varies greatly, ranging from 0 to 2197 for nano patents developed by firms and 0 to 824 for those developed by research institutes and universities. On average, the number of patents cited by firm patents is remarkably higher than that of university patents, with a mean of 30.44 for the former group and 8.75 for the latter. This shows that, as expected, innovation performance carried by firms is more closely related to the market than innovation performance carried by university.

The distribution of cited literature is highly skewed (Popp 2017). Hence we take natural logarithms for the independent variables (except average year of cited WoS publications which is a variable with normal distribution). Given that there is a time lag in receiving citations, it is of importance to take the age of patents into consideration. The likelihood ratio test has been performed by comparing the models without year dummies and those with year dummies. The test shows that the latter group fits significantly better than the former group (prob>chi2=0.0000). Therefore, regressions in this study all include year dummies[7]. To a lesser degree, the national economic environment may also influence the patenting performance in one country. Hence, we use the cluster function in the regression models[8] to capture the differences between countries[9].

Table 1 documents the regression results of three samples: 1) all patents, 2) firm patents and 3) university patents[10]. Given that *Scientific scope* (nr_cited_pub) and *Variety of scientific resources* (nr_all_country) are highly correlated, these two variables are included in separate models.

Technological scope (i.e. number of cited patents) has a significant and positive effect on the dependent variable (i.e. forward citations of nano patents) in all models, including the full

[7] Based on the publication years of patent applications.

[8] The Akaike information criterion (AIC) and Bayesian information criterion (BIC) both suggest that models with country clusters perform better than those without.

[9] Based on the assignee countries.

[10] Firm-university collaborated patents are not included in the sub-samples.

sample (Models 1&2), sub-sample of firm patents (Models 3&4) and sub-sample of university patents (Models 5&6). The second variable, *scientific scope* (i.e. number of cited WoS publications) is positively significant in all three models. This implies that a wider scope of scientific references is likely to lead to a higher patent quality. With regard to the third variable, *newness of scientific knowledge*, there is a slight difference between firm patents and university patents. The coefficient values are higher and more significant for university patents (Models 5&6) than those firm patents (Models 3&4), indicating that citing more recent scientific publications is more beneficial to university inventions. This issue will be further explained later in Table 2 & 3.

Regarding the issue whether the quality of science plays a role, results in Table 1 show that the *quality of cited scientific articles* (forward citations of cited WoS publications) has a positive effect on the quality of citing patents. This positive effect is highly significant for all models at the 0.01 level, indicating that a patent developed based on a group of high-quality scientific research is likely to receive more forward citations itself in the future.

Variety of scientific knowledge resources has a significant coefficient in the full sample models. However, such effect is found to be higher and more significant in the firm patent group than the university patent group. This points out that it is more valuable for firm patents (rather than university patents) to refer to scientific knowledge from various origins. Year dummies are highly significant for all models, which can be explained by the time lag of forward citations.

Note: 1) The dependent variable is the number of forward citations received by each nano patent. 2) Standard errors in parentheses, *** p<0.01, ** p<0.05, * p<0.1. 3) The results on 15 year dummies are not reported in this table.

Following the results in Table 1, we extend the analysis to explore the effect of knowledge resources on patent quality. We use WoS references from the U.S. to represent knowledge flows from advanced countries, and WoS references from China to represent knowledge flows from emerging economies. The knowledge recipients are divided into home and foreign groups. The former stands for the group of patents developed in the same country as the knowledge resource origin, and the later represents the group of patents developed by foreign countries. Considering the aforementioned different nature of inventions developed by different organizational types, firm patents and university patents are tested separately in Table 2 and Table 3.

For patents developed by firms, Table 2 includes four sub-groups, i.e. knowledge flows from the U.S. (sub-groups 1&2) and knowledge flows from China (sub-groups 3&4). Results show that, similar to the aggregated results in Table 1, *technological scope* (i.e. number of cited patents) has a positive and significant effect on the quality of citing patents, irrespective of countries of knowledge resources.

The results on *scientific scope* (i.e. number of cited publications) are mixed, as they depend on the organizational types and knowledge resource countries. A wide scientific scope has a significant positive effect on patents citing scientific articles from the U.S. (Models 1&3). However, for the sample with scientific knowledge flows from China, this variable presents a non-significant effect in the home patent group (i.e. Chinese patents, in Model 3) while a positive and significant effect is presented in the foreign patent group (i.e. patents developed by foreign countries, in Model 4).

In terms of *newness of scientific knowledge*, there is also a noticeable difference between different patent groups. In the sample with knowledge flows from the U.S. (Models 1-4), a more significant and slightly higher coefficient is observed for home patents (Models 1&2) compared to foreign patents (Models 3&4). In the sub-sample for patents receiving knowledge flows from China (Models 5-8), the effect for home patents is almost twice as high as those for non-Chinese patents. That is, more recent scientific research is more beneficial to home patents developed by Chinese inventors (Models 5&6) than patents developed by non-Chinese inventors (Models 7&8). In general, this shows that more recent scientific knowledge is beneficial to patents developed by inventors from the same countries as the knowledge origins. For crossing knowledge flows – i.e. the knowledge resource country is different from the patent inventor country – relatively earlier knowledge is more beneficial. Among all the different groups, Chinese patents citing scientific knowledge from China have the highest coefficients, 0.08295 in Model 5 and 0.08804 in Model 6.

Similar to the results in Table 1, the quality of cited scientific articles is statistically significant and positive in all models in Table 2. This supports our hypothesis that high-quality scientific knowledge can help improve the quality of patents.

The *variety of scientific knowledge resources* has a significant and positive coefficient in sub-groups 1 & 4. This is consistent with the variable of scientific scope. In Model 4 (sub-group 2), this variable is positive but non-significant, in line with the variable of *scientific scope*. This shows that, in most cases, it is more beneficial to have a higher level of *variety of scientific resources* or *scientific scope*. However, for Chinese patents developed based on Chinese science (sub-group 3, Model 6), the *variety of scientific resources* has a negative contribution to the quality of citing patents. This indicates that more scientific publications and a higher diversity of author countries do not lead to a higher quality in the Chinese patents developed based on Chinese science.

Table 3 reports the regression results for university patents, with distinguished scientific knowledge flows from the U.S. and China. Most of the regression results in Table 3 are in line with those in the firm-patent sample in Table 2. A major difference is that, compared to Table 2, the coefficients of *technological scope* are not significant in sub-group 3 in Table 3. This indicates that the scope of technological background does not have a significant effect on the quality of Chinese patents developed base on Chinese scientific knowledge. Similarly, on average *variety of scientific resources* in sub-group 3 is also remarkable lower than the mean of this variable in the U.S., i.e. 1.8 v.s. 4.3 for firm patents and 1.5 v.s. 4.5 for university patents. This indicates that, for the group of Chinese patents developed based on Chinese science, *scientific scope* and the *variety of scientific knowledge resources* is considerably low.

Conclusions

In order to understand what types of scientific knowledge can help generate impactful technologies, this paper uses nano patents data collected from the Derwent World Patents Index (DWPI) and extracts both patent citations and non-patent citations (NPCs) for each patent. By linking the quality of patents with the characteristics of NPCs (including their information from Web of Science), this study investigates how science can help improve the quality of new technologies.

On the one hand, our study shows that science can help improve the quality of patents in many different ways. This, in accordance with Sorenson and Fleming (2004), emphasizes the importance of S&T linkages. On the other hand, this study stresses that the science-technology linkage patterns can differ across countries. There are also differences between organizations, as well as knowledge origins. This corresponds to the heterogeneous nature of knowledge sources stressed by Audretsch and Link (2019). In our empirical study, we find that more recent scientific knowledge has a more significant contribution to the quality of patents. In most cases, this effect is stronger for university patents than for firm patents. Compared to the U.S., China's patents seem to benefit greatly from recently published scientific research. This might be explained by the fact that, as an emerging country, China's patents focus more on emerging technologies, rather than mature technologies. Hence, more recent science is more relevant in China.

Our results suggest that a wider scientific scope and a high level of variety of scientific resources do not always lead to a higher patent quality. A specific case is that, when Chinese patents are developed based on Chinese science – in which case the scientific scope and variety level is very low – the significant positive contribution is missing. To some extent, in line with Appio et al. (2017), this proves our hypothesis that public science with a larger scope does not always lead to higher-quality inventions. Irrespective of patent types or country origins, our findings show that the quality of cited science has always been crucial in affecting the quality of citing patents. A high-quality scientific base can help lead to a high-quality patent.

Abstract

Science, technology and innovation (STI) policy evaluation is an increasingly recognized practice around the world. But what is its real role in the formulation, implementation and/or maintenance of these policies? Considering that not only the results but also the quality of evaluations can influence policy design and execution, meta-evaluation, meta-analysis and evaluation synthesis studies are fundamental. This research-in-progress paper aims to present an effort of evaluation of STI policy evaluations in the Latin American context. The research is part of a broader initiative named Science and Innovation Policy Evaluations Repository (SIPER), coordinated by Manchester Institute of Innovation Research (MIoIR). The paper main contributions are: (i) a literature review about the concepts of meta-evaluation, meta-analysis and evaluation synthesis and applications of these tools in STI field; (ii) a framework of indicators to evaluate STI policy evaluations; (iii) an overview of STI policy evaluation in Latin America.

Introduction

The focus of this work is to present an on-going experience of collecting, coding and analyzing Science, Technology and Innovation (STI) Policy Evaluations in Latin America (LA), with emphasis in the evaluation design and methods. In this work, STI policies and programs are understood as any type of public intervention (in partnership or not with non-governmental actors) that promotes scientific and technological development and innovation at international, national, regional or local levels.

The research is part of a broader initiative named Science and Innovation Policy Evaluations Repository (SIPER), coordinated by Manchester Institute of Innovation Research (MIoIR). SIPER is a central source of knowledge on science and innovation policy evaluations. Its aim is twofold: (i) to provide on-line access to a unique collection of policy evaluations, located at a single location; and (ii) to allow policy learning by providing an informed analysis of the database contents that is both searchable by policy makers and other stakeholders and which provides the basis for additional academic analysis.

The paper is organized in three sections: a literature review about meta-evaluation, meta-analysis and evaluation synthesis and its applications in STI field; SIPER methodology and procedures adopted in the Latin American case; and the partial results about STI policy evaluation in Latin America.

Literature review

Meta-evaluation, meta-analysis and evaluation synthesis are not new concepts or instruments. They have been built and implemented since the late 1960s, but there is still ground for research about their operation and use. Jacob and Affodegon (2015) reinforce this point for the specific field of meta-evaluation, arguing that despite its evolution, there are still few studies and many challenges to be faced. For meta-analysis and evaluation synthesis, despite the abundance of studies (especially in the field of health sciences), the challenges of operationalization are equally important.

Meta-evaluation, a concept coined by Michael Scriven in the late 1960s, can be defined as the evaluation of the evaluation (Scriven, 2009; 2010) and is usually oriented to the measurement of the quality of a given evaluation, based on the criteria of validity, credibility, clarity, suitability, utility and generalization (Stufflebeam, 2001). It is, therefore, an evaluation that has the own evaluation as an object of interest (Furtado and Laperrière, 2012).

According to Jacob and Affodegon (2015), this quality measurement is related to the description of how the evaluation was performed (or even how it is being or will be performed) and a judgment based on standards of what can be considered a "good" evaluation. In this sense, evaluating the evaluations systematically assists both the improvement of evaluation techniques, contributing to the evaluators' own work, as well as the view on the robustness and integrity of the evaluation, contributing to its use (Hanssen et al., 2008; Firme and Letichevsky, 2010, Stufflebeam and Coryn, 2014, Jacob and Affodegon, 2015).

Scriven (2009) claims that a partial meta-evaluation is better than none. This means that although ideally a meta-evaluation involves checking the data collected, the evaluation design, analyzes and conclusions, making only one or more parts of this set can contribute in the directions indicated above - to improve the evaluators' work and the subsequent use of recommendations derived from an evaluation. This is a finding related to the very effort required for a complete meta-evaluation. An example in this line can be found in Cahalan and Goodwin (2014). The authors recover data from an evaluation of the Upward Bound US program conducted by a consulting firm (Mathematica) and discuss both the methods and the results achieved by this assessment, consistently indicating the biases of the original assessment.

It is also worth to distinguish the concept of meta-evaluation from two other related concepts: meta-analysis and evaluation synthesis, more oriented to organize and aggregate results of a series of evaluations (Good, 2012). According to Weiss (1998), Stufflebeam (2001) and Edler et al. (2008) the term meta-analysis refers to statistical analyzes that result from the integration of data, especially quantitative, obtained in a set of evaluation studies. In this sense, meta-analysis contributes to summarize the effects of a given policy in certain aspects, from the measurement performed in different evaluations. According to the authors, the great advantage of this instrument is to increase the volume of data available for analysis; the risks associated with it lie precisely in the biases that arise from the objectives and the ways in which different evaluations were carried out, the differences in the quality of these evaluations, as well as the selection of the studies that will compose the meta-analysis. Care and control of these differences are fundamental in the application of this type of instrument.

For its turn, evaluation synthesis, also discussed by Edler et al. (2008), is similar to meta-analysis in the way it is oriented to integrate a set of evaluations. However, evaluation synthesis seeks to answer different questions about the evaluated object, which result from evaluations with different focuses and methodologies, allowing a new interpretation of the different findings. It should be emphasized that the conceptual delimitation between the concepts of meta-analysis and synthesis of evaluations is not consensual since there are many papers that do not use statistical analysis and that call themselves meta-analyses. In this work, it is proposed that these concepts are not used interchangeably.

Despite the differences, there are authors who approach the three concepts, such as Cooksy and Caracelli (2005) and Edler et al. (2008), who understand that meta-evaluation in its original sense can serve as a step in the selection of good evaluations for later conducting an evaluation synthesis or meta-analysis. The meta-evaluation can also serve as a step after the elaboration of an evaluation synthesis or meta-analysis, as a way of analyzing the quality associated to the way of conducting these studies and/or their results.

In order to answer how these efforts apply in STI Policy field, a broad search was made in the Web of Science, Scopus and Scielo bases, combining terms related to STI (science, technology, research, R&D, innovation, policies, programs) with the exact terms of the concepts and tools (meta-evaluation, meta-analysis and synthesis of evaluations), from 2000 to 2018. The refinement of the articles in order to select only the pertinent ones was carried out from three subsequent activities: elimination of duplications, reading of abstracts and reading of articles. At the end, 32 articles were selected.

The articles were published in 26 different journals. All journals had only one article, with exception of Research Evaluation, in which 7 articles were identified. There was a total of 89 different authors, 5 of them with 2 publications: Edna Solomon co-authored with Mehmet Ugur, Erik Arnold, Jari Hyvärinen and Patrik Gustavsson Tingvall. We found 11 meta-analyzes, 11 synthesis of evaluations, 7 meta-evaluations, 2 combinations between meta-evaluation and meta-analysis and 1 combination between meta-evaluation and evaluation synthesis.

There were two main kinds of evaluations used as inputs to these studies. The first one included evaluations of the effects of R&D expenditures and/or research funding in different dimensions, especially in business and economic performance, including evaluations of research and innovation funding agencies and of EU Framework Program. The second group included evaluations of the effects of information and communication technologies (ICTs) in different dimensions, particularly in education.

The studies used as sources of data evaluations exercises mainly described in scientific papers and technical reports. From the methodological point of view, there was variation between the tools. Meta-analysis studies used mainly meta-regression. The evaluation synthesis studies used mainly descriptive statistics and qualitative analysis. The meta-evaluations were also centered on descriptive and multivariate statistics, focusing on the design of evaluations and, secondly on their quality and use. Finally, it is highlighted that two articles used meta-evaluation as a previous step to conduct a meta-analysis or an evaluation synthesis.

From this literature review, it can be concluded that, although they are important tools to understand evaluation results (policy contributions), as well as their quality (evaluation practice), meta-evaluation, meta-analysis and evaluation synthesis studies still have restricted use in the STI field. In general, the papers do not report the use of the results of the researches, although they consider their findings very useful for the formulation of policies.

The research presented in this paper contribute to filling this gap by conducting a comprehensive meta-evaluation study of STI policy evaluation in LA that also serve as a step in the selection of relevant evaluations for later running an evaluation synthesis or meta-analysis.

Methodology

The research follows a three-phase methodology: collect, code and analyze. Collection phase refers to identifying evaluation studies (papers, working papers, evaluation reports) of STI policies in LA countries. As defined by SIPER project methodology, qualified evaluations to be included in the study are those: (i) on science, technology and innovation policy; (ii) evaluating a clearly identifiable, specific program or group of programs; (iii) having a distinguishable methodology; and (iv) providing some sort of evidence. The searches were oriented to 6 Latin American countries: Argentina, Brazil, Chile, Colombia, Mexico and Uruguay.

Collection was done in four main sources: (i) institutional websites (ministries, government agencies and STI-related development agencies); (ii) academic teams, research organizations and companies dedicated to the study or practice of STI evaluation; (iii) journals oriented to STI evaluation; and (iv) world-wide-web in general. These strategies were thought as a way to capture what is available in the selected countries. 153 evaluation documents have been found, divided as follows: Argentina: 26 documents; Brazil: 38 documents; Chile: 35 documents; Colombia: 18 documents; Mexico: 19 documents; Uruguay: 17 documents.

Coding phase was dedicated to characterization of collected documents following SIPER requirements based on a survey, which includes:

(1) Related policy measure characteristics (targets, modality, objectives)

(2) Evaluation characteristics: (2.1) Basic (who conducted; timing, purpose; reference to intervention rationale); (2.2) Topics covered (i.e. outputs, outcomes, additionality, goal attainment, gender issues, degree of satisfaction of stakeholders); (2.3) Design; (2.4) Data collection methods; (2.5) Data analysis methods; and (2.6) Quality Issues.

These topics represent a suitable framework of indicators to evaluate evaluations in STI field, although they miss the satisfaction of the potential users as well as the effective use of evaluation's results. This is for sure a very relevant topic that should be added in a meta-evaluation exercise. Nevertheless, it demands an extra data collection effort from policy makers, since the evaluations themselves generally do not reveal the use that was made from their analysis, conclusions and recommendations.

Up to now, 134 Latin-American evaluations were coded and uploaded in SIPER repository, which also contains 565 evaluations from other countries.

Finally, the last phase comprehends the use of codified information in order to discuss state-of-art of STI evaluation practice in LA.

Findings and discussion

Preliminary results show that STI policy evaluation activity in LA is recent and heterogeneous across countries. Some countries, such as Chile, Argentina and Colombia, have a greater tradition in this field: they started their evaluation efforts before other countries and continue along of the whole period for which the collection occurred. The types of policies that have most been targeted for evaluation are direct funding, such as research grants, subsidies and credit. Direct financing through scholarships and indirect financing, in particular through tax incentives, are also highlighted (Figures 1 and 2).

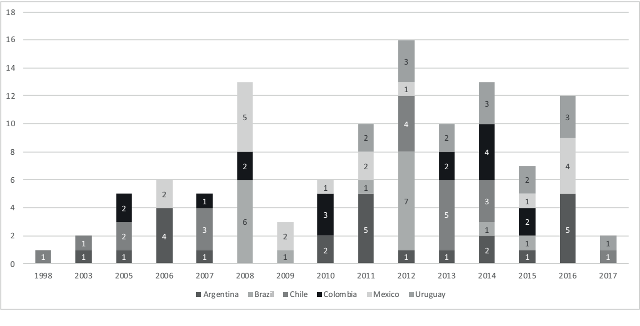

Figure 1: Evaluations by country

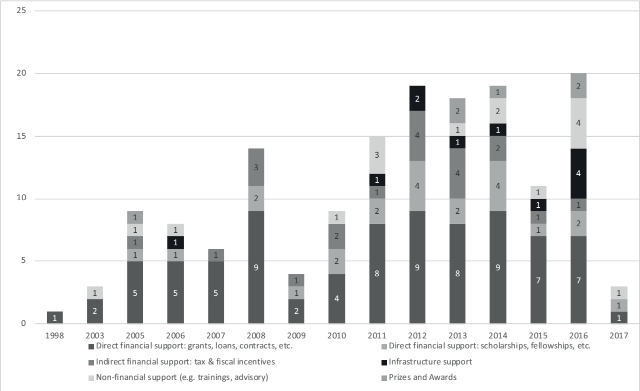

Figure 2: Typology of Policies

Having the national research and innovation systems from these countries as a background, it is possible to assume that the evaluations are in line with research and innovation activities that are being conducted in those nations, with the exception of policies fostering graduation studies through master and doctorate scholarship, that are very common in those countries but not so commonly evaluated.

Evaluations were mostly conducted externally by independent bodies (63%) or by a combination of external contracting by independent bodies and internal staff (27%). Execution by government external teams is minority in the sample. The same happens with non-Latin-American evaluations: 82% were conducted externally, by independent bodies or within government.

Regarding the timing, interim evaluations, that is, those carried out after a certain period of implementation of the policy or program, stand out (116 from 134 evaluations). Ex-post evaluations - those carried out after the end of the implementation period of the policy or program - amount to 12. Finally, 6 ex-ante evaluations were carried out before the implementation of the policy or program. This behavior is similar to non-Latin-American evaluations.

In general, the purpose of these evaluations is a combination of formative and summative (69 documents), followed by only summative (50) or formative (15) evaluations. With only 3 exceptions, the evaluations report the rationale of the evaluated policy or program, either completely or partially. For non-Latin-American evaluations, the ratio for those evaluations that combine formative and summative purposes is even bigger, performing almost 65% from the total, and there were also few cases (19 from 565) that do not report the rationale of the evaluated policy or program.

Quasi-experiments (especially those that use treatment and comparison groups) and non-experiments are the dominant designs, corresponding to 60 and 59 evaluations respectively. There are also combinations between quasi-experimental and non-experimental designs (14 evaluations) and a single evaluation that combines quasi-experiment and an experiment. There is a prominence for non-experimental evaluations in non-Latin-American countries (58% from the total) and also for a combination between non-experimental and experimental evaluations (25% from the total). There are 19 cases using experimental design, solely or in combination with other designs.

Regarding the aspects considered in the evaluation (Figure 3), the focus is on both the results and the impacts, here understood as effects in the long term. Following these aspects, there are the implications for future development of policies / strategies, achievement of objectives, adherence to policy/program (extent to which beneficiaries are attracted), appropriateness to the rationale of the policy, additionality and degree of satisfaction of stakeholders. Little emphasis was placed on mobility, career, networking, gender and minority issues. Differences between Latin-American and non-Latin-American evaluations can be perceived in Figure 3. Appropriateness of rationale, design and goals are aspects more emphasized in those non-Latin-American evaluations when compared to Latin-American ones.

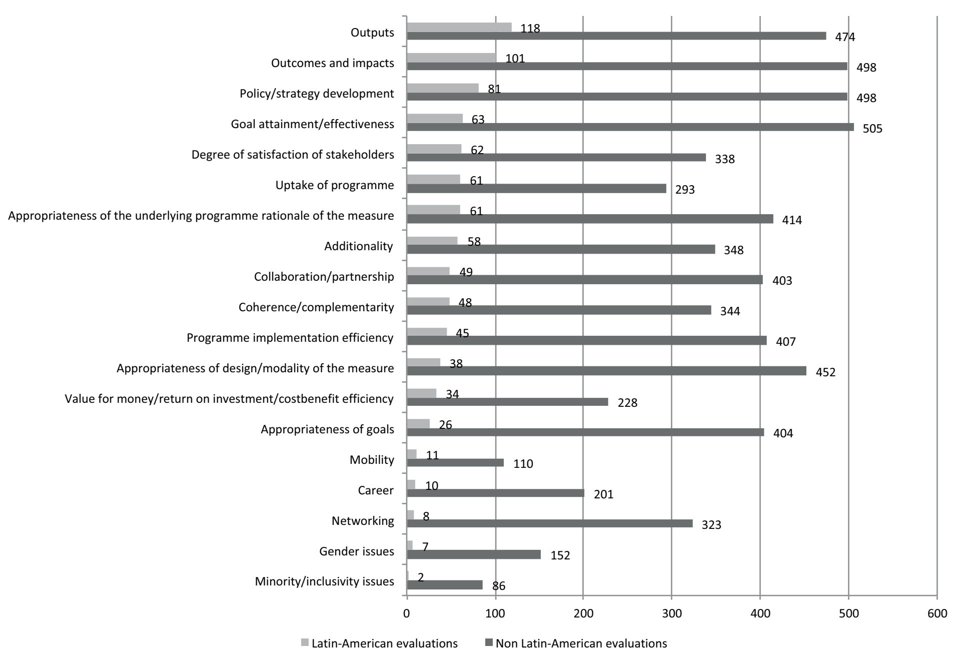

Figure 3: Aspects of the program examined by the evaluations

Of the 118 evaluations that measure policy outputs, only 41 have focused on identifying the quality of these results. Regarding those that measure the long-term impacts of policies (101 evaluations), there is an emphasis on the use of scientific and technological, social and economic indicators. On the other hand, education, competencies and environmental indicators were not highlighted. Of the 56 evaluations that measured economic impact, 28 analyzed cost-benefit or returns on investment. A set of 58 evaluations measures additionality, 29 of which analyze only output additionality, 9 input additionality and 1 behavioral additionality. There is also a combination of input and output additionality (11) and of the three types (5). Additionality is understood here as the difference between the policy/program in terms of investment (in the case of additionality of input), generation of results (in the case of additionality of output) and behavior of beneficiaries.

Regarding the data collection of the evaluations, it is worth noting the use of existing databases (116 evaluations); surveys (64); interviews (52); focal group/workshop/meetings (25); and analysis of scientific publications (19). For non-Latin-American countries, in addition to these tools, evaluations employ peer-reviews, formalized data on intellectual property and site visits.

Considering data collection methods, descriptive statistics (117 evaluations) and econometrics (60 evaluations) are strongly emphasized. Descriptive statistics is also emphasized in non-

Latin-American evaluations, followed by qualitative or quantitative analysis of texts; case-study analysis; input/output, cost/benefit, return on investment analysis, and finally econometric analysis.

Conclusion

The analyzes carried out so far indicate a growing movement towards the institutionalization of STI policy evaluation practices in Latin America, in line with the growing importance of these policies and the perception of their contribution to the countries' economic and social development. However, there are few variations on the methodological designs and indicators used, evidencing the need for substantive advances in this field. Complementary analyzes should be carried out after collection and characterization of all evaluations, seeking to identify the occurrence of a relationship between the analyzed variables, as well as the countries' profile regarding STI evaluation. Further comparisons among STI policy evaluation in LA and other regions and investigating the real use of evaluation results for policy decision-making are also promising developments of this research.

Abstract

Understanding the evolution of science and technology is essential to comprehend the innovation dynamics of humankind. One crucial in the last finding was the shape of citation distribution, which is following a heavy-tailed distribution with a large disparity. Also, many studies suggested that there is the rich-get-richer effect on the citation that highly cited literature tend to get a new citation easier than other literature; in other words, there is a strong memory of the citation. To understand the mechanism behind the memory, we investigate 21 years of citation evolution through systematic analysis entire citation history of 42,423,644 scientific literature published from 1996 to 2016 contained in SCOPUS. We define a compensated citation measure that separating citation preference of individual article from the influence of the various external agents: i) journals, ii) author countries, and iii) disciplines. From the compensation, we found that the influence of the journal is overwhelming the other two factors. We also developed a generative agent-based model to account for such results, indicating the combination of Matthew effect of the citation and pre-established preference for the journals may result in current status. Our approach sheds light on the unbiased and quantitative understanding of scientific evolution.

Introduction

The progress of science and technology is commonly considered as standing on the shoulders of giants, which means new scientific discoveries are building upon previous researches. A citation is standardized mean to give credit for trail-blazing pioneers. Naturally, the number of citation became a common measure to assess the influence of the scientific outputs, e.g. papers, books and proceedings (Bornmann & Daniel, 2008). One notable finding in the late 20th century was the distribution of paper citation tends to follow a heavy-tailed and highly skewed distribution, such as power-law (Price, 1976; Redner, 1998) and log-normal distributions (Thelwall & Wilson, 2014; Thelwall, 2016). In other words, there are a few but a considerable number of scientific literature that receives an extremely large number of citations compared to ordinary scientific outputs. Researchers have identified substantial factors influencing citation distributions. As the illustrative example, the influence of disciplines (Albarrán *et al.*, 2011) and journals (Yun *et al.*, 2018) have been studied. However, the majority of studies mainly focused on a snapshot of accumulated citation count from the publications, yet hardly considered yearly evolution of the citation count, influenced by various factors.

In this research-in-progress, we have extended our previous study on the influence of the journal for the citation distribution to the influence of disciplines and author countries (Yun *et al*, 2018). For this purpose, we investigate the distributions of three normalized citation counts and compare the degree of memory effect for the normalization citation counts. In particular, we examined the complete 21 years of history for every scientific literature to assess their citation growth over time; thus, we mainly focus on the yearly acquired citation for the scientific literature.

Rescaled measure and impact of the journals, disciplines, and countries.

We begin with the data analysis of the entire SCOPUS CUSTOM XML DATA as of 22 August 2017, which covers from January 1996 to August 2017. This dump includes 42,423,644 academic pieces of literature with title, journal, disciplines of the journals (ASJC; All Science Journal Classification), author information (including author countries), and citation records in XML format. We use the records regardless of the document type to avoid possible bias due to the sampling. We consider the discipline of a paper with a classification scheme of Scimago Journal & Country Rank(SJR) consisting of 309 subject categories refined from the ASJC scheme (Gómez-Núñez *et al.*, 2011) because some of the subject categories in ASJC are barely used (Wang & Waltman, 2016).

In this study, we mainly focus on the impact of journals, disciplines, and author countries by extending of our own previous study on the impact of the journals for the citation distributions (Yun *et al*, 2018) that we proposed the rescaled measures of citation as follows:

$$C_y^*(a) = \frac{C_y(a)}{\sum_{a\in j(a,y_p)} C_y(a)/N\left[j\left(a,y_p\right)\right]}$$

where $C_y(a)$ is the citation count of article a in the cited year y, and $j(a,y_p)$ is the set of articles published in the same journal and published year (y_p) of the article a. Although this measure is primarily defined to compensate influence of the journals for the citation count, the measure is easily extendable for the various factors by altering the normalization group $j\left(a,y_p\right)$ for the normalization factor $\sum_{a\in j(a,y_p)} C_y(a)/N\left[j\left(a,y_p\right)\right]$. For example, if $j(a,y_p)$ is the set of articles published in the same and published year (y_p), and belonging to a specific discipline or author countries, the measure indicates the citation count compensated the influence of discipline or author countries. One should note that one paper can belong to more than one discipline or countries; thus, we take geometric mean for the normalization factors for such cases. In short, we generalize the rescaled measure as follows:

$$C_y^*(a) = \frac{C_y(a)}{\left[\prod_{k=1}^{n_k}\left[\sum_{a\in j_k(a,y_p)} C_y(a)/N\left[j_k\left(a,y_p\right)\right]\right]\right]^{\frac{1}{n_k}}}$$

where $C_y(a)$ is the citation count of article a in the cited year y, and $j_k(a,y_p)$ is the set of articles published in the same discipline (or country) k and published year (y_p) of the article a. A parameter n_k is number of disciplines (or countries) that an article a belonging. The rescaled citation presents the relative citation among the most similar scientific literatures in terms of the age and various factors, *i.e.* journals, disciplines, and author countries.

As the first step, we investigate the best fit model distributions for three normalized and one raw citation count with the Maximum Likelihood Ratio (MLR) methods (Clauset *et al.*, 2009) by testing six candidate distributions: i) power law (PL), ii) power law with an exponential cut-off (PLE), iii) lognormal (LN), iv) lognormal positive (LNP), v) exponential (EXP), stretched exponential (StEX). If the Maximum Likelihood Estimator for a certain distribution is superior to all other distributions, we consider the distribution is the most suitable model distribution for the citation counts based on its own meaning (Clauset *et al.*, 2009). What we observe is the mixture of three distributions for the raw citation with the slight dominance of log-normal for the raw citation, while all three rescaled measure shows the dominance of power-law with an exponential cut-off (Figure 1). Journal normalized citation shows a strong preference of power-law with an exponential cut-off, yet other two normalized measures also show the considerable amounts of log-normal distributions (Figure 1). In other words, discipline and country normalization do not show the universal distribution for entire publication and citation years, meanwhile journal normalization gives the more universal distribution of power law with an exponential cut-off.

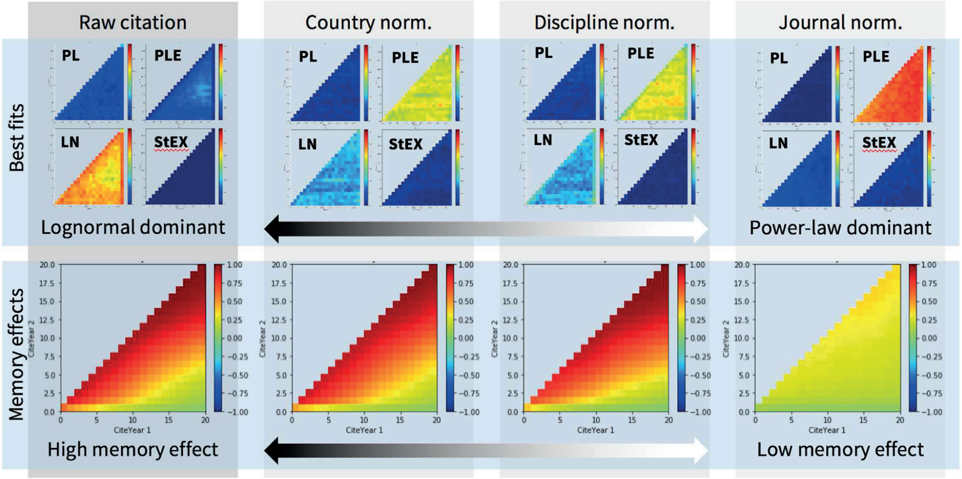

Figure 1. Best fit distributions count for the 309 SJR classification and memory effect of scientific literatures published in 1996 for the raw and normalized citation measures. Results of raw citation and journal normalized citation are taken from our own previous study (Yun *et al,* 2018).

In our own previous study (Yun *et al.*, 2018), we also claimed the existence of strong memory effect of citation, or *the rich-get-richer phenomena*, citation count influenced by the previous citation counts (Borner *et al.*, 2004; Wang 2014). Again, we utilize Pearson's correlation coefficient for different cited years, from lists of the citation count the papers published in the same year. Interestingly, the influence of early citation lasts more than a decade for the raw citation, discipline normalized citation, and author country normalized citation (Figure 1). Although discipline and country normalization also removes the memory effect slightly, the memory effect still exists after normalization. In contrast, journal normalized citation shows insignificant correlations across the cited years (Figure 1). In other words, the influence of the journal is overwhelming the other two factors for the memory effect.

Figure 2. Schematic diagram of the agent-based model.

Agent-based model of citation memory

To prove the dynamics behind the memory effect of the citation, we introduced a simple agent-based model that both popularities of the journals and previous citation history of the paper influence the preference of the new citation. The model begins with a pool of the *N* papers that can be cited in the simulation (Figure 2). There are also N_j journals that papers are belonging to. Journals have their own pre-established popularity P_j, which is randomly drawn from the log-normal distribution of mean μ and standard deviation σ. In our model, we considered the author's citation is driven by the popularity of the paper. Many factors may affect the choice for the citation, but we assumed three: i) popularity inherited by the journal, ii) popularity due to the number of the previous citation of the paper, and iii) decaying of the influence of the previous citation due to the aging. For every step, a new paper cites k articles in the citation pool with a probability $Prob(i) \propto P(i) \times C^*(i;t)$ (see Figure 2). Here, $P(i)$ is the popularity of the journal paper i belonging to. $C^*(i;t)$ indicates the sum of the citation of paper i with decaying due to the aging as follows:

$$C^*(i;t) = 1 + \sum\nolimits_{c \in C(i)} \frac{\exp\left(-\frac{a(c;t)}{T}\right)}{k}$$

where, $C(i)$ is the set of citations that paper i received since the onset of the system, $a(c;t)$ is the age of the citation c at time t, T is temporal decaying rate for the citation history, and k is the number of reference for a new article. For the simplification, we fix the parameters $P(i)$, k, and T as the constant. We also perform the similar journal normalization for the model as we considering a year in the model as the *N* steps of the simulation, which is same as the number of the papers in the citation pool.

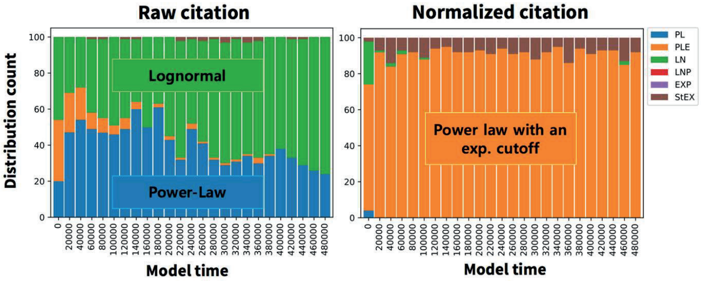

Figure 3. The best fit distributions of the agent-based model. The simulation is performed under following parameters: number of papers *N* = 20000, number of journals N_j = 500, number of ensembles *e* = 100; popularity distribution parameters mean $\boldsymbol{\mu = 0.0}$, standard deviation $\boldsymbol{\sigma = 1.6}$, decay parameter $\boldsymbol{T = 3 \times 10^4}$. We consider model year is simulation time of 20000, which is same as the number of papers in the system

The results of the agent-based model are consistent with the data analysis. The best fit distribution for the raw citation is lognormal with a considerable amount of the power-law (Figure 3; compare with Figure 1). As the model time goes by, the model shows a stronger log-normal prevalence. In contrast to the raw citation, most (journal) normalized citation is observed as the power law with an exponential cut-off (Figure 3; compare with Figure 1). Although our model disagrees with the second popular distribution of the raw citation (power-law with an exponential cut-off for the empirical data and the power-law for the model data), the model successfully reproduces the change of best fit distributions for the journal normalization.

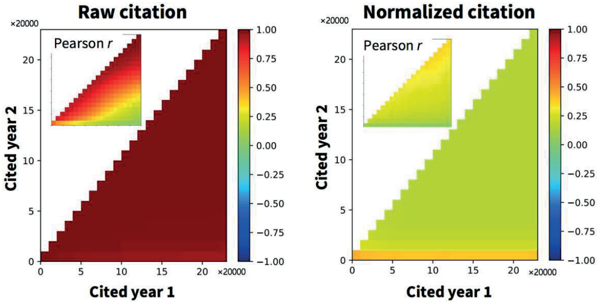

Figure 4. Memory effect of the agent-based model (large panels) and empirical data (insets). For both cases, we perform journal normalization. The simulation is performed under following parameters: number of papers $N = 20000$, number of journals $N_j = 500$, number of ensembles $e = 100$; popularity distribution parameters mean $\mu = 0.0$, standard deviation $\sigma = 1.6$, decay parameter $T = 3 \times 10^4$. We consider model year is simulation time of 20000, which is same as the number of papers in the system

In addition to the best fit distributions for the raw and normalized citation count, our model also reproduces the trend of memory effect for the yearly acquired citation reported in Figure 1. As shown in Figure 4, the interrelationship between the number of citation between two different years produces a similar result. For both model and data, we observed a significant correlation between across the citation years, which is varnished by the journal normalization. Although the model failed to imitate the decay of correlation with more than 10 years of time differences, it successfully demonstrates the result of the normalized citation (compare Figure 1 and 4).

Discussion

In this research-in-progress, we explored the influence of the journals, disciplines, and countries on the citation through a massive history of metadata in SCOPUS over the past two decades. We show a strong memory effect can be compensated by the journal normalization, yet discipline and country normalization do not give much impact on the memory effect. We suggest that in-depth analysis of other factors that influence the number of citations, e.g. impact of authors and institutes may be promised to enhance the impact of our approach, yet left for the further research due to the difficulty of the disambiguation. We hope to refine our agent-based model with more factors can improve the quality of the model, especially reproducing the decaying of memory more than 10 years of time differences. Going one step forward, if data-driven analysis accompanied by the proper model, it provides the evidence to understand the evolution of the knowledge formation, as we hope.

Abstract

This paper aims to increase our understanding of which barriers may hinder researchers from undertaking interdisciplinary research (IDR). IDR is research that builds on a set of theories, concepts, tools, data, and methods that are not available within a single discipline or specialty. IDR is a common policy priority because it is expected to generate knowledge to address complex societal problems such as climate change, sustainability, population ageing, etc. In order to understand the perceived barriers to undertaking IDR, we surveyed three groups of stakeholders in the UK Higher Education (HE) system: (i) researchers, (ii) managers in HE institutions, and (iii) managers in research funding organisations. We first defined three samples of potential respondents: a sample of 16,625 researchers based in UK HE institutions from 2013 to 2015 (this sample was stratified by regions at NUTS-1 level); a sample of 1,080 managers in 15 universities representing a cross section of UK HE institutions; and a sample of 539 managers in research funding organisations. The survey response rates were about 13%, 33%, 17% in the case of researchers (i.e. 2,183 responses), managers in HE institutions (i.e. 367 responses), and managers in research funding organisations (i.e. 94 responses), respectively. The survey provides evidence of discrepancies of the perceptions of barriers to IDR around four main areas (i) collaboration, (ii) career, (iii) evaluation, and (iv) funding across stakeholder groups and research areas. This has policy and managerial implications for the ease with which these can be addressed.

Introduction and related literature

Interdisciplinary research (IDR) has attracted widespread attention from researchers, policy makers, and funders (e.g. Horton, 2017; National Academy of Sciences, 2005; Nurse, 2015). Strong expectations exist about the role of IDR in providing solutions to address the most complex challenges in climate change, sustainability, and global health, which single disciplines may not be able to address. For example, there is increasing consensus among policy makers that addressing major issues such as antimicrobial resistance requires a global and interdisciplinary response (Syed, Ducrotoy, & Bachmann, 2016).

This has resulted in growing pressures on research organizations to steer their 'monodisciplinary' research trajectories towards interdisciplinary approaches (Spelt, Biemans, Tobi, Luning, & Mulder, 2009). A large variety of actors is involved in this process: from funders – focussed on the design of policy instruments to support an efficient allocation of funding as well as to create a 'protected space' for researchers to undertake IDR – to research managers/administrators in Higher Education (HE) institutions – facing resource distribution and research evaluation challenges – and the research teams actively involved in IDR. Actions and behaviours of these groups towards IDR are likely to be shaped by the perception that these groups have of which factors may incentivise or hinder researchers to undertake IDR efforts. In this regard, our understanding remains non-systematic, thus posing considerable challenges on devising organisational and policy mechanisms capable of addressing barriers to IDR at different levels.

The paper attempts to address the following question: how do barriers to IDR are differently by different groups of stakeholders involved in the research process? To address this research question, we build on a large-scale UK-based survey analysis involving researchers working in different disciplines, managers in HE institutions, and managers in funding organizations.

Academic and policy research on IDR has been extensive (e.g. Frodeman, Klein, & Mitcham, 2010; Wagner et al., 2011). This includes conceptual and theoretical efforts on defining IDR and building typologies of IDR (e.g. Barry, Born, & Weszkalnys, 2008; Huutoniemi, Klein, Bruun, & Hukkinen, 2010; Lattuca, 2001; Miller, 1982), and studies focused on the development of methodological approaches and indicators to evaluate IDR. Pioneering quantitative approaches have extensively built on the analysis of text mining and citation patterns in bibliometric data (e.g. Bromham, Dinnage, & Hua, 2016; Fox, 1999; Leydesdorff & Rafols, 2011; Porter & Rafols, 2009; van Raan & van Leeuwen, 2002), while more recent efforts have started to capitalise on the increasing access to textual sources and advancements of text-mining techniques. Researchers have also argued that statistics are necessary, but not sufficient to capture the complexity of research process (Klein, 2008). For this reason, qualitative measures of IDR have been also proposed. These include measures of IDR collaboration based on participants' self-assessments (Hall et al., 2008; Mâsse et al., 2008).

Evidence has been provided that IDR and research impact are positively related. For example, the relationship between IDR, as measured on the basis of indicators derived from the list of cited references in publications, and publication citation count has been found to be positive. According to Uzzi et al. (2013), publications with 'unusual combinations' of prior works (which can be conceived as a proxy of IDR) are twice as likely to be highly cited than publications with 'conventional combinations' of references. Chen et al. (2015) found that top 1% most cited papers are those with the highest levels of IDR (as assessed on the basis of the Simpson Index of the disciplinary classification of the journals of the cited referenced). Yegros-Yegros et al. (2015) found also a positive relationship between IDR (as assessed on the basis of the disciplinary diversity of publication references, i.e. variety, balance and disparity of the WoS categories of cited references) and citation count. Yet, this relationship seems to be curvilinear (inverted U-shape). Similar findings were also reported by Wang et al. (2015).

Evidence of the positive relationship between IDR and research impact have been also found in the impact cases submitted for the 2014 UK Research Excellence Framework (REF). The text-mining analysis of the full-text of such cases revealed that two-thirds of REF Impact Cases could be classified in two or more disciplinary areas, thus they could be considered to be at least multidisciplinary (Kings College London & Digital Science, 2015).

Although these conceptual and methodological research efforts have remarkably increased our understanding of interdisciplinarity, considerable challenges remain in evaluating IDR (Klein, 2006; McLeish & Strang, 2016).

We aim to contribute to this literature by providing a more systematic understanding of which barriers hinder IDR according to the perspective of different actors involved in the research process. It is worth noting that there is a lack of consensus around the definition of IDR (Lau & Pasquini, 2004). A variety of terms have been associated with the concept of IDR: (i) interdisciplinarity as including research approaches that "[…] integrate separate disciplinary data, methods, tools, concepts, and theories in order to create a holistic view or common understanding of a complex issue, question, or problem" (Wagner et al., 2011); (ii) multidisciplinarity as when "Theory, methods, and interpretive standards of the different disciplines are employed. Interpretation of the results from different disciplines typically occurs post hoc, often from the perspective of one discipline that may emerge as dominant within the project" (Rossini & Porter, 1979); (iii) trans- disciplinarity as "Trans-sector, problem-oriented research involving a wider range of stakeholders in society" (Klein, 2008); and (iv) cross-disciplinarity, often used to describe the previous three research modalities.

The complexity of defining what is a 'discipline' from the conceptual and empirical points of views and how individual researchers may differently perceive the boundary of their discipline are at the core of this debate (e.g. Huutoniemi et al., 2010). This paper does not aim to enter into the philosophical and epistemological debate on IDR. For the purpose of our empirical analysis, we define IDR *as research activities that cross the boundary of a single discipline or specialty*.

Data and Methods

We conducted a survey analysis targeted to three main groups of stakeholders in the HE system: (i) researchers, (ii) managers in HE institutions, and (iii) managers in funding organizations. Our empirical analysis focuses on the HE system in the United Kingdom.

We designed a 20-minute survey on the basis of a literature review and input received from three workshops with stakeholders. These workshops were facilitated by the Higher Education Funding Council for England (HEFCE) and involved representatives of researchers (21 participants), managers in HE institutions (15 participants), and managers in funding organizations (9 participants) – for more details about the organisation of the workshops, please refer to Davé et al. (2016). The survey was structured along four groups of barriers – i.e. career, funding, collaboration, and outcomes – and was opened to respondents from March to May 2016.[1] For comparative purposes, most of the survey questions were shared across the three groups of stakeholders. However, the survey was also adapted to each group to explore barriers to IDR that could not be explore in all the groups.

To identify our target populations of researchers, managers in HE institutions, and managers in funding organizations, we developed three different empirical strategies. These strategies are described below and summarized in Table 1.

In the case of researchers, our target population is represented by all research-active individuals employed in UK HE institutions. We assumed a researcher in a UK HE institution to be research-active if the researcher was corresponding author of at least one publication from 2013 to 2015, i.e. three years before the survey opened. We used publication data from Web of Science to define a frame population that is as close as possible to the target population (de Leeuw, Hox, & Dillman, 2008; Heeringa, West, & Berglund, 2010). More precisely, we identified all publication records from 2013 to 2015 including at least one author based in the UK as reported in authors' affiliation addresses. This led to an initial sample of 566,957 UK publications of which 219,182 publications (39%) had corresponding authors' email addresses ending with the ".ac.uk" extension. From this sample, we extracted 109,698 distinct email addresses of UK corresponding authors. These email addresses were then matched with a list 164 UK HE institutions (e.g. "sussex.ac.uk" was matched with "University of Sussex"). The NUTS-1 level code of each HE institution was then identified and used to draw a sample of 16,625 email addresses/researchers stratified by region.

In the case of managers in HE institutions, our target population included all individuals responsible for managing research at UK HE institutions. We define our frame population as all individuals responsible for managing research as reported on UK HE institutions' websites. These included roles such as Pro-Vice Chancellor, Head of Department, Head of Faculty, Head of School, Head of Doctoral Studies of Department, Head of Programme, Head of a Unit of Assessment (REF2014), etc. We selected a sample 15 UK HE institutions to include institutions

[1] The survey also explored incentives for stakeholders to undertake IDR. The results of this analysis are not presented in this paper.

from all UK nations, small and large HEIs, and specialized and non-specialized institutions.[2] The websites of these organisations were searched to obtain contact details for research managers from across the whole of these targeted institutions. The list of identified managers and associated email addresses was sent senior managers in the sampled institutions to ensure accuracy. This approach enabled us to build a sample of 1,080 managers.

Table 1. Sampling strategy.

Survey	**Researchers in HE institutions**	**Managers in HE institutions**	**Managers in funding organisations**
Target population	Research-active individuals employed UK HE institutions	Individuals responsible for managing research at UK HE institutions	Staff at UK-based funders involved in the allocation of funding resources to HE institutions
Frame population	Corresponding authors of publications from 2013 to 2015 employed in UK HE institutions: (i) 566,957 UK publications in WoS (ii) 109,698 email addresses with the "ac.uk" extension (iii) Matching between email extensions and 164 UK HE institutions	Individuals responsible for managing research as reported on UK HE institutions' websites: (i) HE institutions' websites to compile a contact list (ii) Senior managers' inspection of contact list	Staff at UK-based funders involved in the allocation of funding resources to HE institutions (i) RCUK funding bodies' website: AHRC, BBSRC, EPSRC, MRC, NERC, HEFCE, HEFCW, SFC, DEL (ii) Funders that issued at least three calls (+£1,000) as listed in Research Professional in the 365 days to May 10 2016
N	105,839 (96% of UK HE institutions)	Unknown	118 (RCUK funding bodies) 421 (Other funders)
Sample population	Region stratification (NUTS-1)	15 HE institutions (representative of region, size, specialisation)	All identified
N	16,625	1,080	118 (RCUK) 421 (Other funders)
Responses	2,183	367	27 (RCUK) 67 (Other funders)
Response rate	13.1%	32.6%	22.9% (RCUK) 15.9% (Other funders) *[Average 17.4%]*

Source: Authors' elaboration.

[2] We defined a HE institution to be "large" if more than 600 Full-Time-Equivalent (FTE) researchers were submitted to the 2014 UK REF 2014, "small" otherwise. We considered specialised HE institutions those focused on a specific research area (e.g. Colleges of Arts, Veterinary Colleges).

In the case of managers in funding organizations, our target population includes staff at UK-based funders involved in the allocation of funding resources to HE institutions. To identify our frame population, we first collected the email addresses of managers in RCUK funding bodies (i.e. AHRC, BBSRC, EPSRC, MRC, NERC, HEFCE, HEFCW, SFC, DEL) as reported on the website of these organisations. This led to a first sample of 118 managers in RCUK funding bodies. We then queried the ‘Research Professional’ platform to identify all calls for funding with budgets of more than £1,000 in the 365 days to 10th May 2016. We extracted the contact details reported in these calls, thus identifying an additional sample of 421 managers in other UK-based funding organisations (e.g. charities, foundations).

The survey response rates were about 13%, 33%, 23%, and 16% in the case of researchers (i.e. 2,183 responses), managers in HE institutions (i.e. 367 responses), managers in RCUK funding bodies (i.e. 27 responses), and managers in other funding organizations (i.e. 67 responses), respectively. We perform a survey analysis including, when population data were available, base weights, non-response weights, and post stratification weights to correct for discipline, career stage, and gender bias that may affect the sample of respondents (de Leeuw et al., 2008). The weighting approach is summarized in see Table 2.

Table 2. Response weighting strategy.

Survey	Researchers in HE institutions	Managers in HE institutions	Managers in funding organisations
Base weight $(w_{B_{h,i}})$	Region (NUTS-1)	Nation	-
Non-response weight$(w_{NR_{c,i}})$	Region (NUTS-1)	HE institution	-
Post-stratification $(w_{PS_{l,i}})$	Contract (role) Gender	- (no population data available)	- (no population data available)
Total weight (w_i)	$w_i = w_{B_{h,i}} \times w_{NR_{c,i}} \times w_{PS_{l,i}}$ $w_{B_{h,i}} = \frac{N_h}{n_h}$, inverse probability of selection in stratum *h* (region) $w_{NR_{c,i}} = \frac{\sum_{i=1}^{n_{rc}} w_{B_{h,i}}}{\sum_{i=1}^{n_c} w_{B_{h,i}}}$, inverse probability of responding in cell *c* (region) $w_{PS_{l,i}} = \frac{N_l}{\sum_{i=1}^{n_{rl}} w_{B_{h,i}} \times w_{NR_{c,i}}}$, inverse probability of responding in post-stratum *l* (contract-region) N_h population size of stratum *h* (region) n_h sample size of stratum *h* (region) n_c sample size of cell c (region) n_{rc} response of cell c (region) N_l population size of post-stratum *l* (contract-gender) n_{rl} response of post-stratum *l* (contract-gender)

Results

Preliminary analyses revealed the presence of alignment and misalignment of how barriers to IDR are differently perceived by stakeholder. These analyses are summarized in Table 3.

First, in terms of career barriers to IDR, there is agreement across the three groups of stakeholders that IDR requires a combination of strong disciplinary training followed by training in other areas. There is agreement, but less strong support, on the need of additional training to undertake IDR. Together, these findings indicate a potential barrier to entry greater for IDR researchers compared to mono-disciplinary researchers.

Managers in HE institutions and funding organisations are also more in agreement that researchers' peers see IDR as less rigorous – although researchers indicate less concern on this point. Managers in funding organisations more often perceive that promotion and tenure policies adversely affect those engaged in IDR, than researchers or managers.

Second, in terms of collaboration barriers to IDR, respondents from all three groups agreed that collaboration involving IDR was more challenging due to communication difficulties in IDR teams. There was a more neutral response to the suggestion that IDR required co-location of researchers. Although managers in HE institutions were more likely to favour this proposal than managers in funding organisations. Managers also agreed that IDR was complex to support and needed more resources, while funders agreed on this to a lesser extent (and not significantly less). Researchers were not asked these questions.

Third, in terms of barriers, a considerable proportion of respondents across stakeholder groups perceived that IDR is less likely to be funded than monodisciplinary research: 48% of respondents in the case of researchers, 44% in the case of managers in HE institutions, and 41% in the case of managers in funding organisations. The strength of this perception is strongest in researchers and managers in HE institutions, and significantly less so (but still in agreement) in the case of funders. There was considerable support for the suggestion that this is caused by monodisciplinary perspective of the reviewers. This view was significantly more supported by researchers and their managers than in the case of funders.

There was a significant difference in perception between researchers and managers in HE institutions perceiving the IDR to be seen as more 'risky' during peer review, compared with funders who agreed less with this view. The three stakeholder groups were more neutral on the suggestion that difficulties in producing IDR proposals or perceptions of IDR being of lower quality were to blame for lower funding success.

Finally, in terms of barriers to IDR related to research outcomes, stakeholders agreed that it was more difficult to publish the outcomes of IDR in leading journals, with HE managers significantly more likely to support this view than researchers or funders. Researchers and HE managers also agree significantly more than funders that IDR outputs take longer to produce. There is also agreement across groups (although slightly less in the case of funders) that research evaluation processes undervalue IDR.

Discussion and conclusions

The results of the survey provide evidence that researchers, research managers in HE institutions, and research funders in the UK all recognise a number of barriers to IDR in the UK, including career entry barriers around training, lower funding success for IDR, and IDR being undervalued in research evaluation processes. However, even where there was agreement, funders are sometimes less convinced than researchers and HE managers of the existence of particular barriers. This suggests a need for more close alignment between these groups in order to best address the challenges around IDR.

Table 3. Perception of barriers to IDR across groups of stakeholders [Likert scale from 1 (Strongly disagree/Not at all influential) to 5 (Strongly agree/Extremely influential)].

		Researchers in HE institutions			**Managers in HE institutions**			**Managers in funding organisations**			Rank test (Kruskal-Wallis)
	Barrier	Mean (weighted)	Std. Dev. (weighted)	Obs.	Mean (weighted)	Std. Dev. (weighted)	Obs.	Mean (weighted)	Std. Dev. (weighted)	Obs.	
Career	• A strong disciplinary training is required to undertake IDR	3.81	0.99	2023	3.97	0.91	358	3.93	0.86	85	*
	• Additional training is required to undertake IDR	3.55	1.09	2036	3.47	0.97	357	3.36	0.94	84	
	• Peers in researchers' core discipline(s) consider IDR less rigorous	3.17	1.23	1987	3.50	1.09	354	3.38	0.98	72	***

Abstract

This paper determines the ranking of the publications units of assessment which were submitted to the UK research evaluation carried out in 2014, the REF, which would have been obtained if their submission had been evaluated with the bibliometric algorithm used by the Italian evaluation agency, ANVUR, for its evaluation of the research of Italian universities.

Introduction

The week before Christmas 2014, university offices were abuzz with discussions and dissections of the freshly published results of 2014 "Research Excellence Framework" (REF), the official evaluation of research conducted by UK academic institutions in the period 2008-13. Since the initial dummy run held in 1986, the raison d'être of this peer review based exercise is twofold: to ensure accountability for the taxpayer's investment in academic research and persuading the public of its benefits; to form the basis for the allocation of the annual "block" budget for research, around one quarter of all the funds to higher education institutions (HEIs).

Following the 2008 exercise, the funding agency run a pilot study with a view to replace the expensive peer review with a bibliometric-based assessment, but concluded that "bibliometrics are not sufficiently robust … to replace expert review in the REF" (HEFCE, 2009) and so the 2014 exercise continued to rely on peer evaluation, with an estimated overall cost of approximately £246m (Farla and Simmonds, 2015), comparable to the annual budget of a medium size university, and dividing up at £4000 per academic assessed. The exercise planned for 2021 will also be conducted via peer review, even when several other countries do adopt a bibliometric evaluation, as highlighted in Wang, Vuolanto, and Muhonen (2014)'s survey. The question of the closeness between a peer review and a bibliometric approach is addressed by Bertocchi, Gambardella, Jappelli, Nappi, and Peracchi (2015) in a report on the working method of the economics and management assessment panel in the Italian eValuation of the Quality of the Research (VQR) 2004-10 assessment, which randomly selected some of the journal articles assigned to bibliometric evaluation also to be peer reviewed, precisely to assess to correspondence between the two methods (see also Baccini and De Nicolao (2016) and the reply, Bertocchi, Gambardella, Jappelli, Nappi, and Peracchi (2016)). Mryglod, Kenna, Holovatch, and Berche (2015) assess the correlation between the score and the rank obtained by each institution with the corresponding "departmental h-index" (Hirsch, 2010). The latter paper examines a broader range of research areas than Bertocchi, Gambardella, Jappelli, Nappi, and Peracchi (2015), and reports good correlations in the various subject areas, between 0.36 and 0.89. However, it uses a different set of articles from those evaluated by the REF panels, and indeed, as we explain below, it includes articles written by academics who were not submitted as part of the group evaluated by the relevant REF panel. In the same vein, Harzing (2017) has shown that ranking UK departments according to the "departmental h-index" correlates to the REF power ranking at 0.97.

In detail, we assess the papers which were submitted to the REF, and are included in the Scopus database, using the bibliometric criteria which ANVUR, the Italian evaluation agency, used to assess the outputs published from 2011 to 2014 submitted for the VQR.

We stress at the outset some limitations of the exercise (illustrated in Table 3), which makes its contribution more a template for more analysis than policy advice: there are specific differences between the two evaluations, and we did not adjust the algorithm to account for these. Even then, we find a remarkable correspondence between the methods: in the 18 REF research areas where at least 75% of the outputs submitted to the REF could be evaluated bibliometrically, the average correlation between REF peer review score and the corresponding measure calculated with the ANVUR algorithm is 0.81, and the average rank correlation is 0.76: for the full sample, the figures are 0.63 and 0.6. Correlation is very much higher for other measures of departmental research quality, which consider the size of the unit as well as its average quality: of particular interest to policy makers is the correlation in the funding that would be attributed by the two methods, which stands at 0.995 when the departments with at least 75% of the outputs could be evaluated bibliometrically, and at 0.986 for the whole sample. Moreover, we show that, had the annual funding to institutions been allocated following the ANVUR assessment methods, the outcome would have differed relatively little. The summary result of the correlation in the institutional funding is most striking: if the output submitted had been evaluated with the bibliometric algorithm used in the VQR, with peer review assessing the rest of the institutional submission, the correlation between the actual funding assigned to each institution and the funding it would have received if calculated with the VQR score would have exceeded 0.9997, and hence the difference in funding would have been minuscule.

We close the paper with a simple attempt to uncover association between the closeness of the measure and other institutional variables, finding very little systematic variation.

The 2014 Research Excellence Framework (REF2014)

The REF2014 evaluated the research conducted by 52,000 academic researchers associated to 1911 units of assessment in 154 HEIs in UK. The assessment was carried out by over 1000 experts in 36 panels, one in each area of research, in turn grouped into four "main panels". The full list is in Table 5 below. It may therefore be useful to fix the terminology: we denote as "subject areas" the 350 subject categories in Scopus (finest classification of topics); we will then denote as "VQR research areas" and "REF research areas" the groups of subject areas which were assessed by the 16 VQR individual panels (known as GEV) and the 36 REF panels. In the formal analysis we index with h the subject areas and with i the research areas.

Panels assessed three main dimensions of an institution's activity. (i) individual research outputs consisting, for each member of staff submitted, of four outputs published in the reference period 2008-2013; (ii) the research environment, as described in words by each institution; (iii) the impact of research on the wider society, in terms of knowledge transfer and/or public engagement, as evidenced in case-study reports, numbering one per every eight researchers.

The panels determined the percentage for each of the three dimensions of the activities of each submission to be assigned to the five quality categories, ranging from the best, 4-stars "quality that is world-leading in terms of originality, significance and rigour" to the worst, 0-stars "quality that falls below the standard of nationally recognised work". On Thursday 18 December 2014, the panels' assessments was made public, together with the aggregate profile, obtained as a weighted average of the outputs, environment, and impact components, with the weights 0.65, 0.15, 0.2.

The unit of assessment (UoA) is the group of researchers submitted to a given panel: there was no requirement that all the academics submitted to the unit should be all part of an institutional group, such as a department, a school or an institute. There were also members of one department being submitted as part of a different UoAs. To lighten the exposition we refer as department or unit, the group of academics which an institution submitted for assessment to a specific UoA, but it must be kept in mind that, for example, health economists, behavioural economists, econometricians, political economists, development economists, all working in their economics department were submitted to the "Public Health", "Psychology", "Mathematical Sciences", "Politics and International Studies", "Anthropology and Development Studies" panels, respectively. And indeed, many institutions submitted the entire department of economics to the "Business and Management Studies" panel. The decisions regarding submissions were taken usually at institutional level with the attempt to improve the overall result. With no obligation either to submit all departments for evaluation or to submit all the academic members of each department submitted, HEIs took different approaches to the decision whether or not to submit a researcher at all, some leaving out weaker researchers, other including every academic on payroll. These considerations suggest a loose correspondence between units of assessment and departments which moreover is unlikely to be orthogonal to the quality of the research output and casts doubts on the possibility of extending to all disciplines the approach of drawing on departmental information to map the outcome of the REF taken by Mryglod, Kenna, Holovatch, and Berche (2015) and Harzing (2017).

Outputs can be submitted by an institution as long as the author is employed by that institution on the REF census date, 31st October 2013, irrespectively of where the author was when the paper was written or published.

The environment component is a written submission describing the achievements of the academic department, together with data on research grant income and PhD completions. Impact is assessed by considering written 'case studies', one for every eight academics submitted, accompanied by supporting evidence which shows how the research of the department has brought benefits outside of academia. Unlike output, impact is attributed to the institution where it was carried out, irrespective of which institution is currently employing the researcher responsible for it at the census date. The measures of environment and impact have no correspondence in the VQR and cannot be the object of a bibliometric approach, so we limit our comparison to the output component of the REF.

Table 1. Summary statistics and cross correlations of REF performance by component[1].

	GPA Score	*GPA Outputs*	*GPA Environment*	*GPA Impact*	*Mean*	*St. Dev*
GPA Score	1				2.82	0.433
GPA Outputs	0.93***	1			2.76	0.369
GPA Environment	0.883***	0.71***	1		2.88	0.751
GPA Impact	0.826***	0.578***	0.726***	1	2.98	0.689

Unlike its Italian counterpart, the UK funding agency does not present a single score. Commentators and the public have therefore stepped in, variously aggregating the profiles into single numbers so as to draw ranking of UoA and institutions in national league tables. The most commonly used are the grade point average, GPA, and the research power, RP

[1] Sample size = 1828 departments submitted to REF 2014. For explanation of the components, see main text. *** denotes significance at 1% level.

(Forster, 2015). GPA is calculated as a weighted average of the scores, with the proportion in each category as weight: the GPA of department i's in institution k is calculated simply as:

$$GPA_{ik}^{REF} = \sum_{s=0}^{4} \pi_{ik}^{s} s$$

where π_{ik}^{s} is the proportion of the activity of department i's in institution k which was assessed to be of s star quality. Table 1 shows that the correlation between the three components is high, but not so much as to make it meaningless to assess the three components separately.

The RP is simply the product of the GPA by the number of staff submitted:

$$RP_{ik}^{REF} = n_{ik} \times \sum_{s=0}^{4} \pi_{ik}^{s} s$$

where n_{ik} denotes the number of full–time equivalent researchers submitted by institution k to panel i. Thus, GPA measures the average quality, without reference to the size of the UoA, which is instead taken into account by the RP measure: excluding a relatively weak member of staff would definitely increase the GPA and reduce RP.

While less prominent in the media, the government does determine a funding score formula, FS, which is used to calculate how to allocate the overall "quality related" funding made available to the sector in each year. Universities are free to spend this funding as they wish, with no link to projects or even disciplines.

When designing the funding formula, the government intended to provide incentives towards high quality research, and so it gave high weight to 4* output, specifically four times higher than the weight given to 3* output, and *no weight* to output judged less than 3*. With the above notation, an institution's funding in year t until the following evaluation exercise is given by

$$FS_{ikt}^{REF} = \Phi_t \times \Gamma_i \times (4\pi_{ik}^{4} + \pi_{ik}^{3}) \times n_{ik}$$

where Φ_t is the coefficient (in the jargon the "QR unit funding"), which varies from year to year, and depends on the overall public funding for universities, and Γ_i is a research area specific weight which takes value 1.6 for STEM subjects, UoAs 1-15, 1.3 for intermediate cost research areas such as geography, architecture, sport sciences, design, music, UoAs 16, 17, 26, 34, and 35, and 1 for all other research areas.

Table 2. Correlation between possible measures of performance[2].

	GPA Score	*Research Power (RP)*	*Funding Score (FS)*	*Mean*	*St. Dev*
GPA Score	1			2.82	0.433
Research Power (RP)	0.377***	1		79.62	93.11
Funding Score (FS)	0.508***	0.978***	1	38.197	50.964

Table 2 shows the correlation between these measures, indicating that the size based ones, RP and FS, are fairly close but both rather different from the GPA; the correlation between the number of academics submitted, n, and the GPA score is 0.433, indicating that the low correlation between GPA and RP may be due to institutions pursuing different strategies, some preferring selecting only their best performers, others pursuing the funding associated with larger submissions.

Our main aim is to determine degree of similarity between the REF peer review and the Italian bibliometric measurement. To do so, we calculate the quality scores of the output

[2] Sample size = 1828 departments submitted to REF 2014. For explanation of the measures see main text. *** denotes significance at 1% level.

component of the research activity of the UK institutions that would have resulted if the REF assessment of the outputs had been carried out using the algorithm that was used to assess the quality of the research of Italian institutions. We stress that we do not attempt to perform a comparison between Italian and British institutions. Given the many differences between the set of rules used in the two assessment methods, as illustrated in Table 3, this seems unlikely.

Table 3. Differences between the VQR (Italy) and the REF (UK)[3].

	REF	*VQR*
All researchers submitted	NO	YES
Portability of output	YES	YES
Weight of output in assessment	65%	80%
Period of evaluation	2008-13	2011-14
Census date	31 October 2013	30 November 2014
Number of outputs per person	4	2
Expert panel	YES	YES
Peer Review	YES	depending on VQR subject area
Bibliometric indicators	available: use at the discretion of the panel	must be used for STEM research areas
Peer review by	panel members or other panels	panel members and external reviewers
Overall funding to research area	depending on evaluation	pre-determined *
Funding attributed to	institutions only	both institutions and departments**
Entity assessed	department/unit	individual output

Differences between the results of the two assessment methods could spring from two sources. One the one hand there could be structural differences between the methods, which would be the case if a substantial fraction of the highly cited papers published in prestigious journals were, rightly or wrongly, considered to be of poor quality by the peer reviewers, or vice versa, if peer review assessed as being of top quality many papers published in obscure journals and with low citation counts. On the other hand, there might be systematic difference in the submission strategy of different institutions: for example large institutions may be able to devote more resources to assess internally the quality of each output submitted, while smaller ones having to rely on bibliometric algorithm to select the papers and the academic to submit for evaluation. Of course, a similarity between the VQR bibliometric and the REF peer review assessment could emerge if they did *in general* yield different results, but in the specific case of the 2014 REF, these various factors cancelled each other out. Thus, the nature of our paper can only be suggestive, even though, compared to some of the existing literature, it covers the whole of the research carried out in the UK.

The VQR bibliometric algorithm.

The VQR algorithm identifies a paper by four parameters: (i) the year of publication, $t = 1,. . ., T$, (ii) the subject area, indexed by h, (iii) the number of citations at the census date, and (iv) the journal where it was published. The last two parameters are both turned into a number in [0, 1] by normalising their position in an appropriate distribution. The algorithm computes the

[3] Summary comparison between the VQR and the REF, see text for more details. Information obtained from www.ref.ac.uk/2014 (REF) and http: //www.anvur.it/attivita/vqr/vqr-2011-2014/ (VQR).

* The amount allocated to all the submissions in a given VQR research area is independent of the evaluations given by the VQR panel to the institutions in that research area.

** The round of annual funding is allocated to institutions, but a subsequent law awarded a numbers of posts directly to departments, partly on the basis of their VQR score.

distribution of the citations obtained by all the articles published in research area h in year t; let this be denoted by $\Phi^{C}_{ht}(n) \in [0,1]$. That is, $\Phi^{C}_{ht}(n) \in [0,1]$ is the proportion of papers published in research area h in year t that have obtained n citations or less. Similarly for journals, where the relevant measure is the journal impact metric: $\Phi^{J}_{ht}(n) \in [0,1]$ is the proportion of journals included in the Scopus database as pertaining to research area h that, in year t, had impact metric at most x.

In order to do so, it is therefore necessary to know the world distribution of citations and impact metrics at the earliest available date after the REF census date. We purchased from Scopus bibliometric information (namely the number of citations and the SCImago Journal Rank) on 1/1/2015, for each of the papers submitted to the REF; given the suggestive nature of the exercise, we opted to use data made available by ANVUR, which included these distributions on 1/1/2017. This might generate a measurement error, which however is systematic only to the extent that there are different trends in the citations patterns and the impact metrics of the journals where certain institutions are more inclined to publish.

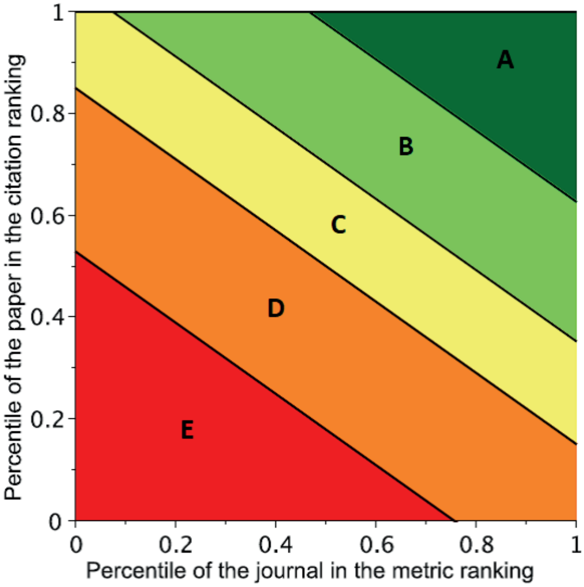

Figure 1. Allocations of products to quality classes.

In the next step of the procedure[4], the unit square $[0,1]^2 \subseteq \mathbb{R}^2$ is divided into five subsets as shown in Figure 1 by four parallel downward sloping straight lines, in such a way that the dark green (A) area[5] is 0.1, the light green (B) and yellow (C) areas are both 0.2, the orange (D) area is 0.3, and the red (E) area is 0.2. Simple computations determine the boundary lines; these are given by $y = a_{it} - b_{it}x$, where a_{it} is the solution in a, for σ = 0.1, 0.3, 0.5, 0.8, of:

$$1 - \max\left\{0, \frac{a-1}{b_{it}}\right\} - \int_{\min\left\{1, \frac{a}{b_{it}}\right\}}^{\max\left\{0, \frac{a-1}{b_{it}}\right\}} (a - b_{it}x)\, dx = \sigma.$$

[4] The procedure is described in detail in Anfossi, Ciolfi, Costa, Parisi, and Benedetto (2016).

[5] The normalisation with the percentiles ensures that the distribution is uniform in the unit square.

The solution is given by

$$a_{it}(\sigma, b_{it}) = \begin{cases} 1 + \frac{b_{it}}{2} - \sigma & \text{if } \sigma \leq \frac{b_{it}}{2} \\ 1 - \sqrt{2\sigma b_{it}} + b_{it}(1 - x) & \text{if } \frac{b_{it}}{2} < \sigma \leq 1 - \frac{b_{it}}{2} \\ \sqrt{2b_{it}(1 - \sigma)} & \text{if } \sigma > 1 - \frac{b_{it}}{2} \end{cases}$$

In the previous equation b_{it} is the slope used to assess outputs in the VQR research area i in year t: it is chosen subjectively by each panel, to reflect the trade-off between visibility of an article and prestige of the publishing journal, and the manner in which it changes with time.
In order to account for the different citation patterns and the fact that more recent papers have less opportunity to collect citations, the slopes separating the areas in Figure 1 increased in absolute value with the year of publication so as to reduce the importance of citation for younger articles.

Table 4. Slopes of trade-offs between citations and impact factor[6].

	VQR				*REF*		
Research Areas	2011	2012	2013	2014	2008-11	2012	2013

Ind. and Inform. Engineering	.4	.6	.9	1.5	.4	.6	.9
Psychology	.4	.6	1	1.5	.4	.6	1

Table 4 reports the slopes that were used in the VQR, and those that we have used to obtain the score for each of the articles we have assessed. The overlap between the REF and the VQR is such that we could use the VQR slopes only for the years 2011-2013. For the other years, we deliberately chose to reduce our degrees of freedom by setting the slopes outside the overlap period to be the same as at its beginning.[7] The first four columns report the coefficients used in the VQR, the last three those we have used to compute the scores of papers submitted to the REF. The score assigned to an article published in a journal included in subject area h in year t depends on the number of citations that it received relative to the world distribution of citation for articles published in subject area h in year t, and on the impact metric of the journal where it was published, again relative to the distribution of the impact metrics of journals in subject area h in year t. In detail, consider an article which was in percentile p^C of the world distribution of citation for articles published in subject area h in year t, published in a journal whose impact metric placed it in percentile p^J of the corresponding world distribution of journals' impact metrics. Then, this article's score is

[6] The slopes of the lines in Figure 1, for different VQR research areas and different years.

[7] The VQR measured citations accumulated up to 2015 of articles published in the 2011-14 period, while the REF looked at 2015 citations of articles published in the 2008-13 period. As a consequence, the REF articles had longer to be cited, and this is why we disregard the slopes used by the Italian VQR in the final year. Moreover, Italian researchers chose the panel to which they submitted their paper, without knowing in advance the slopes which the panel would adopt; in the case of REF, we have relied on the subject area of the publishing journal, which had a correspondence into the Italian Panels reconstructed by Scopus.

given by

$$s_{VQR} = \begin{cases} 1 & \text{if} \quad p^C \geqslant a_{it}(0.1, b_{it}) - b_{it}P^J \\ 0.7 & \text{if} \quad a_{it}(0.1, b_{it}) - b_{it}P^J > p^C \geqslant a_{it}(0.3, b_{it}) - b_{it}P^J \\ 0.4 & \text{if} \quad a_{it}(0.3, b_{it}) - b_{it}P^J > p^C \geqslant a_{it}(0.5, b_{it}) - b_{it}P^J \\ 0.1 & \text{if} \quad a_{it}(0.5, b_{it}) - b_{it}P^J > p^C \geqslant a_{it}(0.8, b_{it}) - b_{it}P^J \\ 0 & \text{if} \quad p^C < a_{it}(0.8, b_{it}) - b_{it}P^J \end{cases},$$

where, in each row, the dependence of a_{it} on σ and b_{it} derived in previous equation is made explicit.

An article is considered as "excellent" (score 1) if it corresponds to the best 10% in the world joint distribution of citations and journal metric; it is assessed as "good" (score 0.7), if it falls within 10% and 30%; it is considered "fair" (score 0.4), if it falls within 30% and 50% and as "acceptable" (score 0.1), if it falls within 50% and 80% of the world distribution. The remaining papers are labelled as "limited", and receive a score of 0.

Approximately 70% of the outputs submitted to REF are published in journals which the VQR had allocated to one or more VQR research areas. We allocated the remaining ones to close VQR research areas by exploiting information on the frequency of publications in journals of a given Scopus subject areas by the academics submitted to a VQR research area. The entire allocation procedure was such that around 46% of the outputs submitted to the REF and contained in Scopus was published in journals which are associated to multiple VQR research areas. Depending on where they fall in the version of Figure 1 of each VQR research area, a given output could have different values of these scores: when this happened, we assessed the given output in all the selected VQR research areas, and then chose the highest evaluation score.[8] After each output was assigned to the corresponding class, the score could be aggregated by averaging or adding up all the scores for each article submitted by members of each unit assessed (department, faculty or university). The corresponding score for each institution *i* evaluated according to the VQR algorithm is given by:

$$GPA_{ik}^{VQR} = 4\pi_{ik}^{1} + 3\pi_{ik}^{0.7} + 2\pi_{ik}^{0.4} + \pi_{ik}^{0.1}$$

where π_{ik}^{s} is the proportion of the articles of institution *i* published in research area k to which the algorithm assigned a score $s_{VQR} = s, s = 1, 0.7, 0.4, 0.1$. Note of course that $\sum_s \pi_{ik}^{s} \leq 11$, but it can be strictly less than 1, as some output may score zero. In previous equation, we calculate the GPA with the weight vector (4, 3, 2, 1, 0) used in the REF, rather that the VQR weight vector, which was (1, 0.7, 0.4, 0.1, 0). The overall correlation between the measures, at 0.998, is very high.

The data

The outputs submitted to the REF can be downloaded as Excel files from www.ref.ac.uk/2014. The total number of outputs assessed is 190962, with 81.09% of the total (154854) journal articles, the remainder consists mainly of chapters in books (7.5%) and books (5.4%).

[8] This is equivalent to assume that the institutions knew in advance the assessment criteria of the potential panels, and would submit each paper to the unit of assessment giving that paper the highest evaluation: again, we have no reason to think that papers with different areas would be systematically concentrated in certain institutions.

Table 5. Summary statistics of the paper submitted to REF 2014.

	Total	154	139468	64.20	19	45	29	5

For each output, the file contains the type of output, the institution that submitted it, the unit of assessment it was submitted to, as well as the DOI, the publication year, the number of co-authors, the title the place of publication and so on. The outputs are distributed evenly in the six years covered by the REF, with the exception of 230 outputs, which have 2007 as publication date.

Scopus returned the required data for 139847 journal articles, the remaining submissions having being published in outlets not covered by Scopus (books, editorials, notes, etc.). In addition, a handful of other products could not be evaluated, for various reasons (301 were of a type not considered by the VQR algorithm, 61 were allocated in the REF published data to an anonymised UoA, and 17 had missing data). The final tally of outputs we assessed was thus 139468. Table 5 presents summary statistics of the output data, showing the research areas where the typical publication outlet are refereed journals.

Results

Our main results are reported in Table 6. Column (1) reports the correlation between the individual GPA scores calculated for the outputs of the various institutions which submitted to the corresponding UoA using the VQR algorithm, and the scores awarded to these units by the REF expert panel. Column (2) reports the rank correlation between these sets of scores. These two sets of correlations are themselves highly correlated (0.973). Both the correlations between values and the rank correlations are positive, and many are very high. GPA scores are averages, and so are independent of the number of academics submitted. Columns (3) and (4) reports the correlations in RP, while columns (5) and (6) reports the correlations in the FS measure, the funding attributed to each unit submitted. In column (5), in the majority REF research areas this correlation exceeds 0.99 with the lowest value at 0.913, for “Music Drama and Dance”. This is extremely high, considering that for this area we could assess less than 17% of the outputs. The weighted average across REF research areas (with weights the output submitted to the REF) is 0.989. The very high values of the correlations even for REF subject areas where relatively few outputs where in Scopus journals can be explained with a correlation between the quality of the outputs submitted to journals and the quality of the books and other forms of outputs in these REF research areas.

The results for the rank correlation are less extreme, due to the fact that many scores are very tightly bunched, and so small measurement errors change little in the absolute scores, but may have large impact in the ranking. Given that the aim of the UK exercise is to assess research, not rank institutions, this is the less relevant of the two correlation measures.

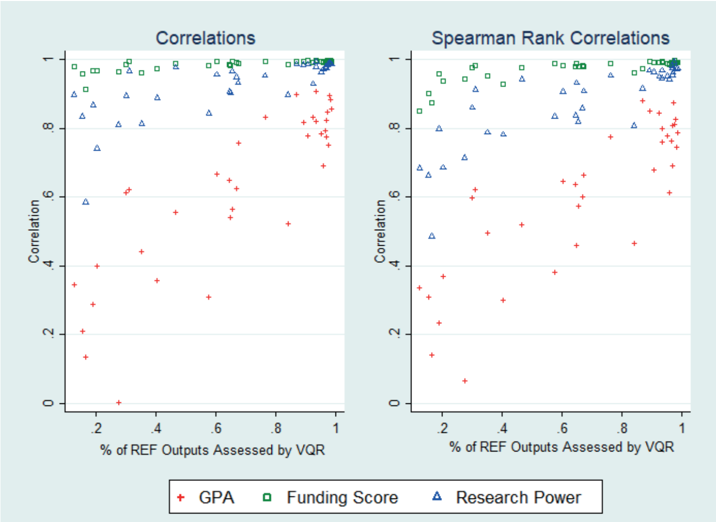

Figure 2. Correlations between performance scores.

Figure 2 illustrates the correlations and the rank correlations in the various units of assessment according to the various measures we have considered. The high correlation in institutional funding is a consequence of the high correlation between the scores, illustrated by the square dots.

Concluding remarks

We have performed an exercise to compare the outcome of the assessment of the research of the 2014 REF with the outcome that would have resulted had the publications which were included in submissions been evaluated, when possible, using the VQR bibliometric algorithm used in the Italian corresponding exercise. While we are keenly aware of the rough and approximate nature of our analysis, we find the closeness of the outcome, especially when comparing size sensitive measures, strongly suggestive that the method could be used to assess the publications at least for the research areas where the main outlet are refereed journals.

These results point to the similarity between peer review and bibliometric criteria (citations and impact factors) when the main outlets are articles published in journals contained in large bibliometric databases. An easy interpretation could be that British peer reviewers were influenced by citation data, in a sort of "informed peer review" (and this was not prohibited by REF rules). A more complex interpretation points to the existence of unobservable quality (creativity, methodological rigour, knowledge of the literature) which can be measured by direct reading (as the reviewers were expected to do) or can be sensed by other scholars, reporting their appreciation by citing the paper. In both cases, the scores of the articles would be correlated, leading to outcomes similar to what we have obtained.

The nature of the research output might be affected by the manner in which it is measured, in a coarse macroscopic version of the Heisenberg Uncertainty Principle. A statement that only journal articles will be considered worthwhile output for assessment would obviously direct academics to try to publish mainly in these outlets. This effect could be particularly strong for early career researchers, many of whose outputs were submitted in the form of working papers, and who might decide or be persuaded to submit their work to less prestigious journals, rather than risk being unable to submit outputs which the rules deem of lower quality.

Acknowledgments

We would like to thank ANVUR for financially supporting this research project. All opinions expressed in the paper are personal and do not involve the Agency. The information and views set out in this paper are those of the authors and do not reflect the official opinion of the European Union, where one of the author is employed. Abstract

The follow-up academic high-impact method of scientific papers is a future-oriented predictive analysis method. This paper uses a new measure of scientific research problem maturity to identify the subsequent influence of new published papers. This paper chooses a special type of highly cited paper, which is the case of delayed recognition of papers. Through the scientific problem maturity method proposed in this paper, it is verified that the relationship and characteristics of scientific research and patent in the process of high citation for the delayed recognition paper reaches after several years of publication is in line with the actual situation. Experiments show that the scientific research problem maturity method, which complement other index or methods, become an effective method to predict the subsequent high impact of newly published papers.

Keywords

High impact paper, scientific research problem maturity, patent growth rate, paper growth rate, academic influence

Articles of Science and Technology are a kind of carrier of knowledge and issues. In face of more and more large amount of latest published articles, how could we identify a new article is going to have high impact in the future? It has been an important research direction on the field of identification of articles with high-impact in the future and academic trend analysis, and meanwhile, has been a focus of field study researchers, valuators and researchers of science policy.

The theory and method of identification for articles with high-impact in the future is an emerging hybrid FTA method. The high-impact scientific papers presented in this paper refer to those scientific research papers that have made significant impact on the development of the subject and the exchanges in the scientific community.

This paper presents a new measurement method namely scientific question readiness level to identify future impact strength of articles. The approach for study readiness level is constructed with an example of delayed recognition papers in the information security field, analyzes and verifies the situation of articles with future high-impact in this field. Delayed recognition papers refer to those papers initially unnoticed or unused， but then was considered very important, whose definition based on times cited in several years after publication. According to experimental study, the approach for study readiness level, is able to reflect the level of high-impact in the future, by means of complementing with other methods is efficient method to predict high-impact strength in the future of articles.

Introduction

At present, the research on the identification methods of high-impact scientific papers in the future is concentrated in three aspects. The indirect indicators are used to predict the subsequent citations of scientific papers, and the social network analysis methods are used to identify key position papers and semantic judgments.

Identification method based on indirect indicators of refracting high impact

If the first-hand evidence or indicators are not available, such as the newly published scientific papers have no or only low citation frequency and number of downloads, indirect metrics are needed. Variable analysis is the method to predict future citations by the characterization data of the paper.

Perneger and Brody think that the number of early hits is a potentially useful measure of the scientific value of published medical research papers (Perneger,2004; Brody,2006). Publication of hit counts by online journals should be encouraged. The paper's scientific value also leads to citation by other researchers. Earlier web usage statistics could be the predictors of later citation impact. Levitt and Thelwall(2008) think that for highly cited articles the prediction of citation ranking of from the sum of citations during their first six years was less accurate than prediction using the sum of the citations for only the fifth and sixth year. Adams (2005) also thinks early citation counts correlate with accumulated impact.Higher citations were predicted by indexing in numerous databases; number of authors; abstraction in synoptic journals; clinical relevance scores; number of cited references; and original, multicentre, and therapy articles from journals with a greater proportion of articles abstracted. Walters(2006) Predicted subsequent citations to articles published in twelve crime-psychology journals, the Author impact is more important than journal impact. Some researchers have carried out the author's reputation and the reputation of the journal on the high citation of the paper. Dalen and Henkens(2001,2005) thinks By means of a citation analysis, several quantifiable characteristics of the articles (characteristics with respect to authors, visibility, content and journals) are strongly related to their subsequent impact in the social sciences. They points out that the reputation of journals plays an overriding role in gaining attention in science.

A study by Malissa A. Schilling and Elad Green(2011) found that several factors, such as search scope or search breadth, search depth, and atypical connections between different research areas, can increase the impact of the paper. The above conclusions are still true even if the academic experience of the author and the success factor of the previously published article are controlled. Researchers such as Boyack (2005) developed a method based on journal importance, reference importance, and author reputation to predict the importance of current papers. According to their report, among the three important variables, journal influence has a strong correlation with the discipline. They suggest that these important factors can be used to rank papers without waiting to accumulate the number of citations. This implies a hypothesis that a paper can obtain more citations by citing more high-cited articles. Some researchers have also paid attention to the prediction of the subsequent citation of the paper based on the relevant indicators of the authors based on different research fields. Kostoff (2007) found that highly cited papers tend to have more co-authors, cite more literature, and write longer summaries and pages. The study by Skilton (2009) found that in the natural sciences, highly cited co-authors and authors tend to be highly cited if they have a multidisciplinary background or come from different regions. Bornmann and Daniel(2006), Tijssen, Visser, & van Leeuwen (2002) conducted research on the citation behavior, paper type, etc.

Identification research based on social network analysis method

The social network analysis method uses the topological indicators in the citation network to predict future citation behavior. Professor Chen Chaomei(2011) studied and established the theory of discriminating scientific turning points through social network methods. N. Shibata, Y. Kajikawa, Y. Takeda (2009)analyzed the correlation between the three centrality indicators in social networks and the number of future citations in two areas. According to the research, although there are only a few citations, the papers with high mediation degree tend to get more citations in the future because those papers connected the knowledge of different fields.

Recognition method based on semantic judgment

In addition to these indicators, will future high-impact papers be identified by other signals? Some scholars have discussed the semantic properties of the paper. Some researchers have proposed evaluation indicators for the quality of the paper. For example, Van Dalen (2005) proposed two indicators, impact and speed, to judge the quality of the paper in 2005, but these two indicators still depend on the calculation of the cited frequency and the first cited time. Related follow-up experiments (wang,MY ,2011,2012)demonstrate that predictions are more relevant to the characteristics of the paper, rather than relying on data sets and classifiers. In terms of combining semantic analysis, many researchers pay more attention to the keywords of the papers, and hope to distinguish the themes and connections of different papers from the perspective of conceptual understanding (Yufeng Zhang,2011). Among them, researchers have proposed the title semantic information, citation link relationship and order as the three dimensions of the frontier of detection research (Luxio-Aroas D and Leydesdorff L,2009). Some researchers combined the method of word co-occurrence analysis to solve the problem of automatic recognition and judgment of word semantics. In recent years, more scholars have used ontology to improve the effect of semantic analysis, and some researchers have conducted related research on the ontology of academic resources (Hao Wang and Xinning Su,2011).

At present, the research on the high influence of the paper in the future is mainly to use the external measurement index of the paper as a surrogate index to measure the future cited trend of the research paper. And it weakens the quality of the paper itself, which is the key feature of whether the paper is cited. Moreover, the existing research only predicts that the future citation frequency of the paper is still slightly single from the perspective of the characteristics of the paper itself. This study adopts the method of judging the maturity of scientific research in scientific papers, not only taking into account the paper indicators, but also introducing patent indicators, reflecting the interaction between scientific research and technology. This method analyzes the characteristics of the maturity of the research problems proposed by the delayed recognition paper, and attempts to propose a method to measure the future high impact of the paper.

Method

The maturity of the research problems

The maturity of the research problems refers to a study that may be at different stages of the research life cycle. It is based on the concept of scientific research life cycle to select the two indicators of scientific paper growth rate and patent growth rate to represent the development stage of scientific research. This embodies the interaction between scientific research and technology – scientific research is transformed into technology, and the development of technology promotes scientific research.

The development of basic research can be reflected by the growth rate of scientific papers, and the development of technology can be expressed by the growth rate of patents. The growth rate of scientific papers is normally distributed, and the growth rate of patents also has the characteristics of normal distribution. Because the production time of scientific papers and patents is inconsistent, the normal distribution curve of patent growth rate lags behind a period of time t[0-n] relative to the normal distribution curve of scientific papers. t depends on the speed at which scientific research problems embodied in scientific papers in the field are translated into patents.

Therefore, this study selects the two indicators of scientific paper growth rate and patent growth rate to construct the research life cycle graph (Fig. 1,2,3). For a specific scientific paper, the stage of the scientific research life cycle of the research problem can be judged according to the position of the two indicators (the growth rate of the paper and the patent growth rate) projected onto the coordinate map.

Usually, the number of scientific papers increases from slow to rapid growth under the stage from the germination to the rapid growth of basic research. Basic research papers on scientific research issues are produced at this stage. At this time, the research activities are mainly distributed among a small number of scientific research groups, and their concentration is relatively high. Furthermore, when scientific research issues have made breakthroughs or caused widespread concern, related scientific papers will increase rapidly, and the growth rate of papers will rise rapidly. Therefore, the basic research papers and related papers of breakthrough research of this scientific research are concentrated in this stage. It’s very important because it covers the basic theories and methods of the research, the breakthrough development or the theory and method of important turning points.

When the technology is in the mature stage, important basic inventions are born. As more and more R&D companies enter the field, basic research is becoming more sophisticated, and breakthrough technologies are constantly emerging. At this time, important basic patent technologies and breakthrough technologies are concentrated at this stage, and these technologies are bound to become technological prototypes for future development technologies. The development of technology has promoted the study of scientific issues. The scientific papers of technology mapping have embodied important technological developments. It is foreseeable that with the in-depth study of scientific issues and the continuous development of technology, its influence is constantly improving.

During the recession, the number of papers slowly fell back to a very small number, and the growth rate of the paper dropped rapidly and tended to zero. At the same time, due to the lack of sustained support and breakthroughs in basic research, the development of technology has entered a period of decline. The number of patent applications per year shows a negative growth, and the absolute value of negative growth rates continues to rise to a high point. At this time, the growth rate of the paper and the growth rate of patents are both negative growth states, indicating that the scientific research problem has entered a recession stage.

After entering the revival stage of basic research, the number of papers represented basic problems have made breakthrough, and the corresponding papers quantity has slowly increased. It has begun to enter a new round of germination. At this point, the negative growth rate of patent growth has declined, and the impact of breakthrough progress on patent conversion has not yet been demonstrated. The positive growth rate of the paper has shown a positive slow increase, indicating that the basic research in this stage has entered the recovery phase.

Therefore, based on the above analysis, we think that the development stage of scientific problems can be characterized by the growth rate of scientific papers and the growth rate of patents. If the research problems are in the stage of germination to the rapid growth of basic research or in the mature stage, it is considered that the scientific paper has a high probability of high influence in the future.

scientific research problem maturity development hypothesis

According to the above analysis, the development process of a field is divided into four stages, namely, the rapid growth stage of basic research, the mature stage of technology development, the stage of decline, and the revival stage of basic research.

We have designed a coordinates of the scientific research problem maturity judgment of the scientific papers (Fig. 1, Fig. 2, Fig. 3). Among them, Fig. 1 simulates the annual growth of the number of papers and the process of increasing the number of patents. Figure 2 simulates the growth of the papers. The rate and the growth rate of the patent growth rate, Figure 3 shows the maturity graph of the scientific research papers based on the paper growth rate-patent growth rate.

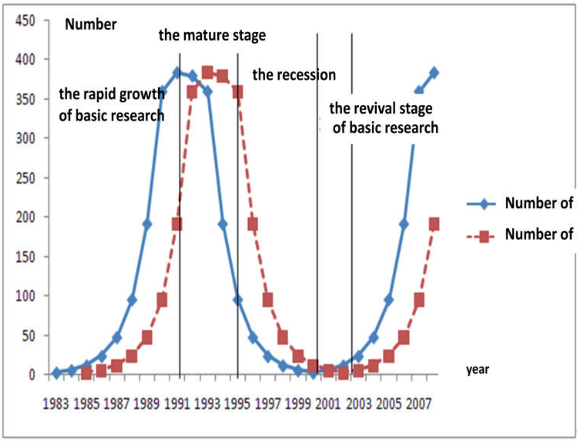

Figure 1 Schematic diagram of the growth of the paper and the growth of the patent

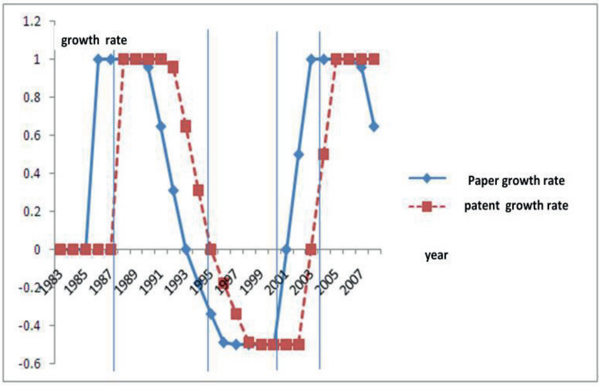

Figure 2 Schematic diagram of the growth rate of the paper and the growth rate of the patent

This study simulates the development process that papers and patents change from growth to recession through data. It builds a model of the relationship between the growth rate of papers and the growth rate of patents (Fig. 3). In Figure 3, the X-axis represents the patent growth rate, indicating the growth rate of the patent for a certain period; the Y-axis represents the growth rate of the paper, indicating the growth rate of the paper for a certain period. The diameter of the circle is determined by the ratio of the number of papers at that time point to the number of patents. The ratio of the number of papers and the number of patents at each time node can be judged initially.

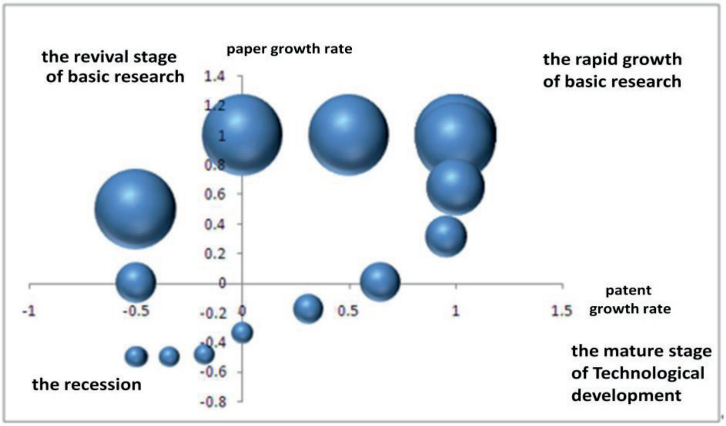

Figure 3 Science and technology paper research problem maturity graph

The various indicators involved in Figure 3 are explained below:

The growth rate of the paper refers to the change in the number of papers published at this time point and the number of papers published at the previous time point, also known as the growth rate.

$$\Delta Ai = \frac{A_i - A_{i-1}}{A_{i-1}} \times 100\%$$

$$= \left[\frac{A_i}{A_{i-1}} - 1 \right] \times 100\%$$

Ai is the number of papers published in the current period;
i=n（n=1,2……,n）

The patent growth rate refers to the change in the number of patents at this time point and the number of patents at the previous time point, also known as the growth rate.

$$\Delta P_j = \frac{P_j - P_{j-1}}{P_{j-1}} \times 100\%$$

$$= \left[\frac{P_j}{P_{j-1}} - 1 \right] \times 100\%$$

Pj is the number of patents in the current period
j=m（m=1,2……,m）

Round area:

$$S = \frac{1}{2} \pi \left[\frac{A_{i=n}}{P_{j=m}} \right]^2$$

$$R = \frac{A_{i=n}}{P_{j=m}}$$

S represents the size of the circle projected into the coordinate map， and is represented by the area;
R represents the diameter of the circle projected onto the coordinate map.
Ai is the number of papers published in the current period;
Pj is the number of patents in the current period;
i=n（n=1,2……,n）
j=m（m=1,2……,m）

Finding

Data and Domain

In recent years, due to the important academic and application value of information security Technology, countries have paid great attention. Research on information security technology has made substantial progress in both technical research and information industry. Therefore, this study selected the scientific and technical literature in the field of "information security technology" as the material for statistical analysis.

The domain data comes from the database in the Web of Science platform, including the core set SCI-EXPANDED, CPCI-S, based on the 12 types of subdivision techniques of the technical system defined in this study. The qualified document types are ARTICLE, REVIEW, PROCEEDINGS PAPER. A total of 14,265 valid search results published in 1995-2004 were obtained, which constitute the data set for the analysis of the Delayed recognition papers in this experimental study.

Considering the difference in the fields, the specific measurement standard for identifying delayed recognition papers in this paper is set as follows: the first three years after the publication of the paper, there is no citation frequency, and in the following years, the frequency of citation increases faster within the statistical time window(Haiyan Wang,2015). The total citation of the paper is the first 30% of the citations of the paper published in the same year. In the field of information security technology, the papers published from 1995 to 2004 were obtained. According to the criteria of the top 30% of the papers published in the same year, we got 41 papers. This article will judge the maturity of these 41 articles separately.

scientific research problems maturity judgment ideas

Firstly, determine the 12 types of technical directions in the field of information security technology, search for the number of papers and patents in the same technical direction and t in the corresponding year; secondly calculate the annual paper growth rate and patent growth rate; then draw maps: the number of papers - the number of patent annual growth process map, paper growth rate-patent growth rate map; Finally, a according to the position of the paper growth rate and the patent growth rate data point projected in the research problem maturity quadrant, we can judge the subdivision technology research problem maturity level, and then predict its development trend.

The idea of analyzing a single paper is as follows. Firstly, determine the research topic of a single paper, and determine the technical direction category of the paper by calculating topic similarity, then judge the development trends of the research problem based on the maturity of the technical direction; Secondly, according to the research theme of the paper, set the search terms, retrieve the number of the same subject scientific papers and the number of patents, calculate the annual paper growth rate and patent growth rate; then draw the annual growth process diagram of the paper - patent, the paper growth rate-the patent growth rate maturity quadrant map; finally, according to the position of the paper growth rate and the patent growth rate data point projected in the research problem maturity quadrant, we can judge the subdivision technology research problem maturity level, and then predict its development trend.

Scientific research problem maturity judgment process

This section analyzes the Delayed recognition papers separately. The following is the analysis process and conclusions of one of the papers.

Paper 1, entitled "An efficient remote use authentication scheme using smart cards", published in the "IEEE TRANSACTIONS ON CONSUMER ELECTRONICS" journal in 2000. This paper discusses a smart card-based remote authentication scheme.

After studying, the paper belongs to the cross-technical direction of identification and authentication technology and cryptography. To determine the technical direction of each thesis's research topic, it can be judged by co-occurrence of the topic words and co-citation of the literature. Because the number of the Delayed recognition papers involved in this study is small, the method of judging the technical direction of each article is adopted. This study separately analyzed the maturity of the cross-technical direction of identification and authentication technology and cryptography.

Technical direction 1: Identification and authentication technology.

According to the above search scheme, 132,718 papers and 25634 patents were obtained. Based on this data, draw the maturity map of the scientific research papers (Fig. 4).

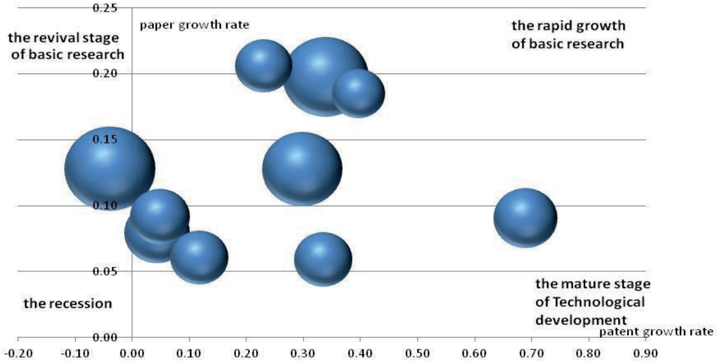

Figure 4 Technical direction 1 scientific paper research problem maturity graph

Technical direction 2: password technology.

According to the above search scheme, 10851 papers and 9075 patents were obtained. Based on this data, draw the maturity map of the scientific research papers (Fig. 5).

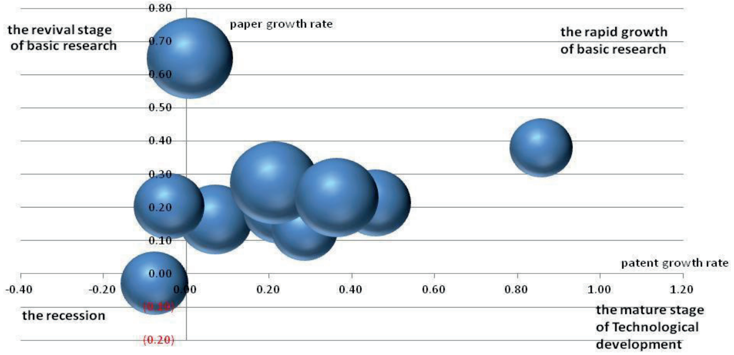

Figure 5 Technical direction 2 Scientific paper research problem maturity graph

For the Delayed recognition article : smart cards, the design search is as follows:

Paper search:(ts=("identification" or "authentication" or "access control") or ts=("cryptanalysis" or "encryption" or "cryptography" or "password")) and ts=(information or network or cyber or software or computer or wireless or communication or data security) and ts=(“smart card”)

Patent search:((TI=("identification" or "authentication" or "access control") or TI=("cryptanalysis" or "encryption" or "cryptography" or "password")) and TI=(information or network or cyber or software or computer or wireless or communication or data security) and …

According to the above search scheme, 460 papers and 203 patents were obtained. Based on this data, draw the maturity map of the scientific research papers (Fig. 6).

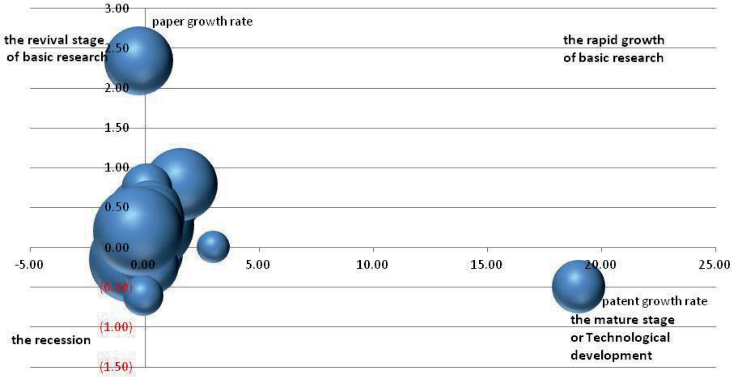

Figure 6 Science paper research problem maturity graph

For Smart Card applications and trends in this research topic:

The data points of the paper growth rate and patent growth rate of the smart card theme are projected in the first quadrant of the research problem maturity model—the rapid growth stage of basic research, the third quadrant—the mature stage of technology development, the fourth quadrant—the revival of basic research stage. According to the definition of this model, the theme has experienced the germination, growth, maturity and revival stage of basic research after new technology improvement.

In the period of rapid growth of basic research and the revival of basic research, it can predict its future high impact - becoming a highly cited paper, it is in line with the actual situation of the Delayed recognition papers. Taking the smart card thesis as an example, according to the performance of the number of papers, the smart card technology experienced a rise, a turn, and then rise, the development of technology, stagnation and continuous change, then making the field undergo a renaissance stage. This revival phase is shown in the fourth quadrant in the maturity graph.

Discussion and Conclusions

It can be seen from the analysis of the existing research that there are still some shortcomings in the identification of subsequent high-impact papers, and the recognition angle or method is slightly single. The follow-up academic high-impact method of scientific papers is a future-oriented predictive analysis method. This paper uses a new measure of scientific research problem maturity to identify the subsequent influence of new published papers. This paper chooses a special type of highly cited paper, which is the case of delayed recognition of papers. Through the scientific problem maturity method proposed in this paper, it is verified that the relationship and characteristics of scientific research and patent in the process of high citation for the delayed recognition paper reaches after several years of publication is in line with the actual situation. Experiments show that the scientific research problem maturity method, which complement other index or methods, become an effective method to predict the subsequent high impact of newly published papers.

At the same time, we also see that this study verifies the development of a single paper through the development of domain themes, and it is aimed at the macro or meso level, applied to the discipline planning of research institutions and the development support of the national science and technology output stage. However, this method cannot directly face micro-evaluation, such as the application of personal scientific evaluation. If it needs to be applied to personal scientific evaluation, other auxiliary indicators should be introduced.

Abstract

The popular social media platforms are now making it possible for scholarly articles to be shared rapidly in different forms, which in turn can significantly improve the visibility and reach of articles. Many authors are now utilizing the social media platforms to disseminate their scholarly articles (often as pre- or post- prints) beyond the paywalls of journals. It is however not very well established if the level of social media coverage and attention of scholarly articles is same across all research disciplines or there exist discipline-wise variations. This paper aims to explore the disciplinary variations in coverage and altmetric attention by analyzing a significantly large amount of data from Web of Science and Altmetric.com. Results obtained show interesting patterns. Medical Sciences and Biology are found to account for more than 50% of all instances in Altmetrics. In terms of coverage, disciplines like Biology, Medical Science and Multidisciplinary Sciences have more than 60% of their articles covered in Altmetrics, whereas disciplines like Engineering, Mathematics and Material Science have less than 25% of their articles covered in Altmetrics. The coverage percentages further vary across different altmetric platforms, with Twitter and Mendeley having much higher overall coverage than Facebook and News. Disciplinary variations in coverage are also found in different altmetric platforms, with variations as large as 7.5% for Engineering discipline to 55.7% for Multidisciplinary in Twitter. The paper also looks into the possible role of source of publication in altmetric coverage level of articles. Interestingly, some journals are found to have a higher altmetric coverage in comparison to the average altmetric coverage level of that discipline.

Introduction

The rapid growth of the Internet and social media has not only transformed the businesses, organizations and society, but has also changed the entire process of scholarly information processing, including article storage, access and dissemination. Not only research articles are being stored in and accessed from online digital libraries, but they are also disseminated through different social media platforms. Scholarly articles are now disseminated and shared on different social media platforms such as ResearchGate, Twitter, Facebook etc. There are some other popular platforms dedicated mainly to dissemination and sharing of academic texts, such as Academia and Mendeley. These academic networks provide wide-range of facilities which can be useful for academics (Gruzd & Goertzen, 2013). Several studies (such as by Williams & Woodacre, 2016) have found these types of academic social networks very informative and relevant for quantitative characterization in research assessments. This social media phenomenon of scholarly articles has become so popular that now a new range of metric have been designed, called alternative metric, to measure the interaction of social media with scholarly information processing (Priem, 2014; Priem & Hemminger, 2010).

Altmetrics is now an interesting area of research where researchers try to analyze the social media coverage and consumption of scholarly articles; and sometimes Altmetric values are even able to predict future citations. However, most of the attention of research in the area has so far been concentrated on measuring correlations and interactions among social media transactions and citation behaviour of scholarly articles. Relatively lesser attention has been paid on measuring disciplinary variations in social media coverage and usage of scholarly articles. This paper tries to address the issue through a comprehensive study involving large amount of data collected from Web of Science and corresponding values from Altmetrics. The main objective is to find out if there exist discipline-wise variations in social media coverage and consumption patterns of the scholarly articles. The data for different platforms (namely Twitter, Facebook, News and Mendeley) is analysed computationally for the purpose. Statistics for some highly visible journals in Social Media and journals with high impact factor are also analysed to understand the role of source of publication and disciplinary variations.

Related Work

There has been some attention of researchers on understanding and analyzing the relationship of social media and scholarly information systems. Some of these studies (Priem, 2014; Haustein et al., 2014; Thelwall & Kousha, 2015; Sugimoto et al., 2017) tried to understand and demonstrate if social media platforms can be used (or not) as a tool to attract more attention towards a published work. Few others (Shema, Bar-Ilan & Thelwall, 2014; Thelwall, 2016; Peters et al., 2016) tried to see if Altmetrics could correlate with citations, with few (Costas, Zahedi & Wouters, 2015a) going to the extent to see if it can complement citations or not. There have also been studies that tried to predict early citations from different platforms of social media, such as Mendeley (Thelwall, 2018), ResearchGate & Google Scholar (Thelwall & Kousha, 2017 a), altmetric.com (Thelwall & Nevill, 2018), and CiteULike bookmarks (Sotudeh, Mazarei & Mirzabeigi, 2015) etc. Country specific Altmetric studies has also been done, such as for India (Banshal et al., 2018) and China (Wang et al., 2016) etc.

Discipline-specific studies of understanding Altmetric coverage and impact have been done by some researchers. For example, a study by Bar-Ilan (2014) mapped astrophysics research output with Mendeley readership behavior using Scopus and Arxiv. Another study (Sotudeh, Mazarei & Mirzabeigi, 2015) analyzed the correlation of research impact and CitedULike bookmarks in Library & Information Science discipline. Few other such efforts are analyzing the relationship between traditional and alternative matrices in psychology literature for the period of 2010-2012 (Vogl, Scherndl & Ku, 2018); online media presence of Swedish articles in humanities in the year 2012 (Hammarfelt, 2014); and evaluation of the impact of Altmetrics in social sciences and humanities research published by Taiwan based researchers (Chen et al., 2015). In a recent work (Htoo & Na, 2017) worked towards alternative metrics across various disciplines of Social Sciences and visualized the significance of ten selected indicators on nine disciplines of social science. However, there has been relatively less attention on understanding disciplinary variations in altmetric coverage of scholarly articles.

The only past works found on Altmetrics with focus on disciplinary analysis are as follows: Holmberg & Thelwall (2014) conducted a study on data from Twitter of ten selected disciplines to map their coverage and frequencies in twitter. Authors here selected ten different disciplines based on their publication size and pattern variations to represent variations in publishing scholarly communication. Similar to this work, authors selected ten disciplines of social sciences and humanities from web of science subject areas to correlate with Mendeley readership (Mohammadi & Thelwall, 2014). However, analyzing overall disciplinary variations in coverage was not the main objective of the paper. Another work (Zahedi, Costas & Wouters,

2014) used a multi-disciplinary approach on different online and social networks to assess coverage and distribution of randomly selected 20,000 articles published between 2005 and 2011. This approach also outlined alternative metrics into seven different broader areas of research. These seven broader areas are classified based on high level classification which classified the research areas as 'Natural Sciences', 'Engineering Sciences' etc. In another related work (Costas, Zahedi & Wouters, 2015b), authors tried to understand the thematic orientation of publications mentioned on social media. However, this paper only uses altmetric data and tries to understand the distribution of the data into various high-level disciplines. It does not measure coverage levels of different disciplines in altmetric. Another work (Ortega, 2015) used thousands of Spanish researchers' profiles to explore the disciplinary behavioral patterns in three online media, namely ResearchGate, Academia & Mendeley. Furthermore, in this analysis the scholarly articles are classified into eight broader areas to visualize the presence and coverage of same discipline's researchers across different platforms. In one relatively recent work (Thelwall & Kousha, 2017b) scholarly communications shared in ResearchGate is being classified into 27 Scopus categories of subject area where the Scopus subject areas are used as it is defined to classify the articles and understand the disciplinary variations.

The present work has focused objective of analyzing coverage levels of articles from different disciplines in Altmetrics. It uses a large amount of data from Web of Science (about 1.4 million records to be precise) and their corresponding entries in Social media platforms. The objective is to understand whether research articles from all disciplines get equal coverage in social media platforms or not. Data is categorized into 14 different well-identified broader research areas/ disciplines and variations in altmetric coverage across these disciplines are identified. Unlike, previous studies the present work mainly tries to analyze altmetric coverage levels of different disciplines and not the disciplinary distribution of altmetric data, pursued by many of the previous studies. Further, a journal-based analysis is also done to understand the disciplinary variation and its impact on altmetric coverage.

Data

The data is obtained from two sources: Web of Science and Altmetric.com. First of all the publication records for the year 2016 are downloaded from Web of Science. The data download process is performed during 1-10th December, 2018. A total number of 2,528,868 publication records are found for the year 2016. This data is then scanned for DOI entries and those records that do not have DOI are removed. This process reduces the data to 1,460,124 records. The second step in data collection involved collecting altmetric data for the 1,460,124 publication records of Web of Science with DOIs. For this purpose, the popular portal altmetric.com was accessed. In altmetric.com, 18 different types of mentions and stats are provided. These comprise of different social network mentions and reads. Out of the 1,460,124 records, a total of 681,274 publication records are found indexed in altmetric.com. Out of these 650,009 records are found with at least one kind of statistics. This corresponds roughly to 45% of data collected from Web of Science having DOI. Though altmetric.com captures statistics from various social platforms; platforms like Twitter, Facebook, News and Mendeley are found to be more popular. We have, therefore, used the altmetric data for these four platforms. The analysis also involves Impact Factor data for different journals, which is collected from Web of Science Reports.

Disciplinary Tagging

To understand disciplinary variations in altmetric coverage, it is necessary to tag each publication record with at least one specific discipline. For this task, each publication record in the dataset is classified into one of the 14 broad research disciplines, as proposed in an earlier work (Rupika et al., 2016). This tagging is done by using Web of Science Category (WC) field information. One record can be tagged with multiple disciplines of research based on its WC entries. These 14 broader disciplines are as follows: Agriculture (AGR), Art & Humanities (AH), Biology (BIO), Chemistry (CHEM), Engineering (ENG), Environment Science (ENV), Geology (GEO), Information Sciences (INF), Material Science (MAR), Mathematics (MAT), Medical Science (MED), Multidisciplinary (MUL), Physics (PHY) and Social Science (SS). Thus the 255-category division of articles in Web of Science is reduced to these 14 broader disciplines and each publication record is tagged with one (or more) broad disciplines. All further analysis on disciplinary variations in altmetric coverage are done across these 14 broad disciplines. The articles are grouped discipline-wise and analytical results are obtained accordingly.

Disciplinary Distribution and Coverage

The first point of analysis was to find out disciplinary distribution of articles in Web of Science & Almetrics and to see if disciplines are distributed in same proportions in Web of Science & Altmetrics. **Figure 1** presents the discipline-wise distribution of research output in Web of Science and altmetric.com. We can observe that some disciplines with higher proportionate distribution in Web of Science have relatively lesser proportion of presence in altmetric.com. In contrast, the Medical Science (MED) discipline accounts for about 30.2% proportion of output in Web of Science whereas in altmetric.com, it accounts for more than 41% of articles covered. Thus, this discipline is over covered in Altmetrics. For many other disciplines, proportionate contribution in Web of Science and altmetrics.com are different. For example, in Web of Science, PHY has the second most published output with contribution of 13.8% whereas its proportionate contribution in altmetrics.com is 7.9%. In Altmetrics, Social Sciences (SS) has the second highest proportionate contribution with a share of 15.4% followed by Biology with a share of 11.9%. Thus, MED and BIO disciplines are more visible in altmetric coverage, being covered in proportion higher than their proportion of published articles indexed in Web of Science. Disciplines like PHY, MAR, MAT, INF and ENG are proportionately less covered in Altmetrics. These results indicate that difference in altmetric coverage proportion of different disciplines are likely.

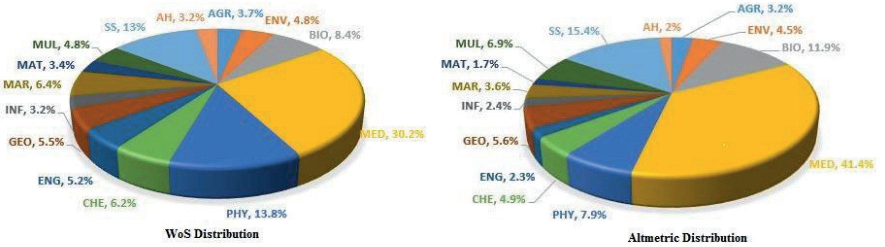

Figure 1. Discipline-wise Article Distribution in Web of Science (WoS) and Altmetric.com

The second point of analysis was to look at each discipline and find out its coverage level in Altmetrics. For this purpose, the Web of Science article counts for different disciplines is taken and altmetric.com is searched to see if they are covered in Altmetrics. This is done through an article-wise lookup in altmetric.com, for each article in Web of Science. **Table 1** shows the counts of articles of different disciplines that are indexed in Web of Science, number of articles found in altmetrics.com, and the altmetric coverage percentage for each of the 14 disciplines. It is observed that there is a significant difference in altmetric coverage percentages. For example, MUL, MED and BIO disciplines have a coverage percentage above 60%, which shows that out of all publications from these disciplines in Web of Science, more than 60% are found covered in Altmetrics. Articles from SS discipline have a coverage percentage of more than 50%. Interestingly, disciplines like ENG, MAT and MAR have less than 25% of their articles covered in Altmetrics. There is, therefore, a clear disciplinary variation in altmetric coverage of articles.

Table 1. Discipline-wise data for altmetric coverage of articles indexed in Web of Science (WoS)

Discipline	*Articles in WoS*	*Altmetric Presence*	*Coverage Percentage*
AGR	53749	21068	39.2
AH	47186	12871	27.3
BIO	123180	77259	62.7
CHE	90959	31670	34.8
ENG	75834	14737	19.4
ENV	69709	29194	41.9
GEO	80477	36420	45.3
INF	46438	15568	33.5
MAR	94117	23571	25
MAT	49385	10865	22
MED	**441032**	**268830**	61
MUL	69445	44778	**64.5**
PHY	201373	51569	25.6
SS	189835	100029	52.7

The third point of analysis was to find out if the discipline-wise coverage patterns are same across different altmetric platforms or if they vary significantly. For this purpose, coverage patterns across four different altmetric platforms, namely Twitter, Facebook, News and Mendeley are identified. **Table 2** shows the data for coverage of articles indexed in Web of Science in different altmetric platforms, corresponding to different disciplines. It is observed that, Mendeley and Twitter have in general higher coverage percentage for most of the disciplines as compared to News and Facebook. Thus, Mendeley and Twitter appear to be more popular altmetric platforms. It can also be observed from the table that there are noticeable disciplinary differences in altmetric coverage of articles. For example, articles from MUL discipline have highest presence in both Twitter & Mendeley with 55.7% and 63.6% coverage followed by BIO with 54.6% & 62.1% coverage. But articles from disciplines like ENG and INF have less coverage in Twitter (7.5% and 9.3%, respectively) and Mendeley (18.6% and 30.5%, respectively). In case of Facebook and News, coverage levels are low, with highest coverage being for MUL discipline of 17.8% followed by MED discipline of 13.7%. In News platform, coverage levels are further low with highest being 13% for MUL discipline followed by 7.5% for MED discipline. Interestingly, articles from ENG discipline have low coverage (7.5% in Twitter; 1.4% in Facebook; 18.6% in Mendeley and 0.5% in News) across all the platforms.

In terms of variations across disciplines, Twitter has the largest variation in coverage ranging from low of 7.5% for ENG to 55.7% for MUL. The variation range is in Mendeley is from 18.6% for ENG to 63.6% for MUL discipline, almost similar as Twitter. Facebook has variation in coverage percentage ranging from 1.3% for INF to 17.8% for MUL discipline. Thus, it is clearly observed that there exist disciplinary variations in altmetric coverage of articles, which varies further across different altmetric platforms. It may also be interesting to see if these variations can be attributed mainly to disciplines or if there are other factors such as the source of publication (journal), which play an important role.

Table 2. Discipline-wise Coverage across Different Platforms of Articles indexed in Web of Science (WoS)

Analysing Disciplinary Variations by Journals

It is quite clear from the discussion in previous section that there are disciplinary variations in altmetric coverage of scholarly articles. An important and relevant question worth exploring here would be to find out if the source of publication (i.e. journal) has any role in higher altmetric coverage of articles. In order to explore this question, a part of data was taken out and analysed. This data comprised of top 100 journals (ranked by Web of Science article count) with the condition that they should have at least 500 articles covered in Altmetrics. These journals are then tagged with a primary discipline, based on data available either on their homepage or Wikipedia. Thus, each journal is categorized into one of the 14 broad disciplines. **Table 3** presents the data for these journals. It can be observed that MED discipline accounts for 35 out of these 100 journals followed by BIO with 24 journals and CHEM with 20 journals. These three disciplines taken together account for about 80% of the top 100 journals. In terms of coverage, MUL discipline has highest number of papers covered in all the four altmetric platforms, though it has only 6 out of 100 journals. In terms of coverage percentage, ENG discipline has the highest coverage in Twitter (86.2%) and Mendeley (85.6%) followed by GEO discipline. Disciplines like MED and BIO have somewhat lesser, but still a significant coverage of articles in Altmetrics. For example, MED has coverage percentage of 59.3% in Twitter and 65% in Mendeley for its articles in the selected sample. Similarly, BIO discipline has coverage percentage 62.2% in Twitter and 69.1% in Mendeley. However, the lesser overall covered disciplines like INF, MAT, MAR are found better covered in this sample. Thus, it is very difficult to conclusively say that publication in a particular journal gives an article a higher chance of altmetric coverage. The disciplinary variations are, however, still seen.

Table 3. Disciplinary Distribution of 100 Most Productive Journals (ranked by WoS count) across Platforms

Discipline	*#of Journals*	*# Articles in WoS*	*Twitter*		*Facebook*		*News Mention*		*Mendeley*	
			#of Articles	*Coverage %*	*#of Articles*	*Coverage %*	*#of Articles*	*Coverage %*	*#of Articles*	*Coverage %*

INF	1	793	482	60.8	67	8.4	76	9.6	524	66.1
MAT	0	0	0	0	0	0	0	0	0	0
AH	0	0	0	0	0	0	0	0	0	0

For a more detailed analysis, the journals and their data are arranged in a different ranking order. **Table 4** shows the data for top 50 journals, ranked both by absolute altmetric counts (on the left side) and by altmetric coverage percentage (on the right side). Looking at left part of the table, it is observed that PHY and CHEM have 13 journals each in the list, followed by 12 journals from MED and 11 journals in BIO. The top few journals having highest altmetric absolute count are MUL discipline. Thus, in terms of absolute counts, MUL, MED, BIO are main disciplines. However, when the journals are sorted by altmetric coverage percentage, then journals from GEO and SS disciplines are also found listed. However, out of 50 journals in the list, 19 journals are still from MED discipline followed by BIO with 16 journals. Interestingly, ranking by altmetric coverage percentage results in only one journal from PHY figuring in the list. Thus, disciplinary variations are seen in this part of analysis as well.

To analyse the impact of journal even further, another sample data was extracted. This sample comprised of 50 journals, ranked by 2016 Impact Factor of journals. **Table 5** presents Web of Science article count for these top 50 journals along with their altmetric counts and coverage percentage. Here, most of the journals belong to either Medical Science or Biological Science. However, of particular interest would be the journals, which are from other disciplines. It is interesting to note that some of these journals have better coverage levels than the typical coverage level of that discipline. For example, the journal 'Nature Materials' has altmetric coverage percentage of 78.6%. Similarly, the journal 'Annual Review of Astronomy and Astrophysics' has an altmetric coverage percentage of 93.6%. Other journals like 'Nature Nanotechnology' has altmetric coverage percentage of 90.1% and 'Reviews of Modern Physics' has altmetric coverage percentage of 88.1%. This is higher coverage percentage than the overall coverage percentage of the respective disciplines. But at the same time several other journals like ‘Progress in Materials Science’, ‘Progress in Polymer Science’, ‘Accounts of Chemical Research’ and ‘Behavioural and Brains Sciences’ have altmetric coverage percentage around or below 50%. However, most of the journals in MED, BIO etc. continue to have higher altmetric coverage percentage. Therefore, it can be observed that there is a definite impact of the discipline of an article in its altmetric coverage. Articles from some disciplines have higher altmetric coverage. There are also some exceptions to this, where some journals in disciplines having relatively low altmetric coverage percentage, have higher altmetric coverage. Therefore, the journal has also some role to play in altmetric attention potential of an article.

Conclusion

This paper presents a comprehensive analytical study to explore whether there are apparent disciplinary variations in altmetric coverage of articles. A large sample of data from Web of Science along with corresponding data from altmetric.com is obtained and analysed. Results obtained show interesting patterns. Medical Sciences and Biology account for more than 50% of all instances in Altmetrics. In terms of coverage, disciplines like Biology, Medical Science and Multidisciplinary Sciences have more than 60% of their articles covered in Altmetrics, whereas disciplines like Engineering, Mathematics and Material Science have less than 25% of their articles covered in Altmetrics. The coverage percentages further vary across different altmetric platforms, with Twitter and Mendeley having much higher overall coverage than Facebook and News. Disciplinary variations in coverage are also found in different altmetric platforms, with variations as large as 7.5% for Engineering discipline to 55.7% for Multidisciplinary in Twitter. Some journals are also found to have a higher altmetric coverage in comparison to the average altmetric coverage level of that discipline, which shows that the source of publication may also have some impact on altmetric coverage of article.

There are however some limitations of this study, which can be addressed in future work. The most important of them is the fact that disciplinary tagging of articles is based on 'WC' field of Web of Science, which classifies an article into a discipline based on its source of publication and not the actual article contents. It would, therefore, be interesting to take some large data sample, classify that into different disciplines using some Machine Learning Classifier (that processes article contents to tag it into a discipline), and then see if the disciplinary variation patterns are similar to those observed in this work. This would also establish the usefulness of Web of Science publication-source based disciplinary classification. Another interesting thing to explore could be to look in detail at the data from some particular journals (that have higher altmetric coverage) and to identify if there are some specific characteristics that helps a journal in attaining higher altmetric coverage, than the typical altmetric coverage level of that discipline.

Acknowledgments

Abstract

International research performance indicators attain increased attention in science policy. More studies point to ongoing global bias in production, composition and assessment of research performance metrics (Rafols et al., 2012; van Leeuwen et al., 2001). This research examines international collaboration. It is an indicator routinely operationalised as co-authorship of articles between organisations by taking organisational address as a proxy of the collaborating country (Katz and Martin, 1997). We use geographical approximation of author heritage rooted in the morphology of the surname and find that in a significant minority of internationally collaborated papers, co-authors are likely to have the same origin. In other words, we observe an overestimation in the international collaboration indicator. The findings indicate that if a significant share of international collaborations of a national research system occurs with researchers previously affiliated with this system, internationally co-authored publications are therefore only ‘inter-national’ on a formal inter-organisational level. This contributes to the evidence that stresses more complex nature of scientific collaboration (Bozeman and Corley, 2004) and may have fundamental implications on the use of international collaboration indicator.

Introduction

In this research, we highlight and analyse the heritage bias in indicators for internationally collaborated research. International research performance indicators are seen to reflect relative competitiveness of a country in producing leading research (in terms of cited papers) and its commercialisation (in terms of assigned patents). An increasing number of studies point to ongoing global bias in production, composition and assessment of research metrics (Rafols et al., 2012; van Leeuwen et al., 2001). When funding, assessment and human resource decisions are made on the basis of indicators, we need to understand what exactly they do and do not tell us.

In science and innovation policy, especially when the issues of development are concerned, countries that have extensive links with other nations are appraised positively by international bodies and in national science policy. Internationalisation is a policy goal in itself, it is seen as important in advancing scientific research (Science Europe, 2014). International collaboration can also be a means to other policy goals. For instance, international collaboration in the European Research Area has been regarded, alongside with mobility, as a sign of increasing integration, and is also designed to level out research capacities of the Western and the Eastern European countries (EC, 2012).

International collaboration as an indicator is not a neutral metric and contains multiple assumptions about what is assumed to be a ‘scientific collaboration’. A landmark paper by Katz and Martin (1997) alongside with later research by Bozeman and Corley (2004) bring forth these assumptions. Most notably, these authors highlight how not ever co-authored publication is a result of a collaboration and not every collaboration results in co-authored publications (see further Youtie and Bozeman, 2014). As these studies expose rich underlying social processes that are not fully captured in instances of co-publication, co-authoring of research articles, books and conference papers has come to be regarded as the dominant way in which scientific collaboration is operationalised and measured bibliometrically.

International scientific collaborations identified this way have been growing at explosive rates and is widely reported (Glänzel, 2001). The assumptions behind what the growth of this metric means have been linked mainly to research inrernationalisation, knowledge exchange and other benefits for the collaborating authors, organisations and countries, because the diversity increases creativity and allows to find better solutions for complex problems (Melkers and Kiopa, 2010). International collaboration is recognised as a capacity-building factor of domestic research indicating the increase in research quality (Bornmann et al., 2015). The criticisms of the growth of internationally collaborated research focus mostly around its uneven distribution, uneven contributions by different authors, and uneven benefits that the authors in central and in the peripheral regions gain from it (Schubert and Sooryamoorthy, 2009). A further example is that patterns of international cooperation in nanotechnology are still centred on the developed countries, which are key nodes in international networks (Shapira and Wang, 2010).

In this paper, we further problematise the assumptions between the supposed gains from international collaboration and the way it is measured. An accepted view of a *bibliometric definition* of international collaboration is an instance when a research output is co-authored by two or more authors affiliated with organisations located in two or more countries. This definition of international collaboration is used in all publications we reviewed for this research. Single-authored outputs with multiple affiliations are not usually regarded as instances of international collaboration. The assumption behind this measurement is, as noted above is to say that when a scientist located in Spain co-authors an article with a scientist located in Germany, it is in effect a Spanish and a German scientists collaborating with each other. Such collaboration entails positive effects related to creativity and diversity (Gkypali et al., 2017), and improves the cohesion between the German and the Spanish research systems. The bias behind these assumptions is the objective of our research.

Research Objectives

We explore the extent and the potential implications of same-heritage international scientific collaboration, taking Russian international collaboration network as a case study. Within the broader goal to unpack the types of interactions and exchanges that occur in international collaborations, we investigate the extent and the role of the bias behind the bibliometric definition's assumption that when authors located in two countries collaborate, these authors are nationals of those respective countries (see Figure 1). This issue becomes increasingly important in the case of when the developing countries aim to connect to the global scientific knowledge flows.

First, we expect to uncover the heritage bias in international collaboration, and we expect it to be substantial. That is to say, that a significant share of internationally collaborated publications between Russia and the rest of the world means co-publication between Russian scientists in Russia and Russian scientists who reside in other countries.

Second, we will investigate the structure of this bias. As shared heritage points to cognitive proximity between two scientists and makes collaboration easier to accomplish, we expect that the extent of same-heritage collaboration will vary depending on the collaborating country, discipline, it will change with time, it will vary depending on which domestic organisation is collaborating, both in terms of the type of the organisation and its geographical location, and depending on the funding received. We also expect to see different same-heritage collaboration dynamics in the centres of excellence and among the ‘star’ scientists.

Figure 1 International Collaboration Bias Structure

By unpacking the inherent international collaboration bias, we, therefore, question the assumed relationship between co-authors in established international collaboration metrics. Ultimately, international collaboration indicators may point to reproduction and reinforcement of relationships between global centres and peripheries, and to knowledge channelling, rather to knowledge exchange.

Background

Heritage links memory, language and places with the construction of identity, values and communities (Smith, 2006). Heritage can be associated with the concept of human capital and links knowledge, skills accumulated in the duration of a person’s life with their behaviour. Studying heritage refers more to accounting for intrinsic and specific features of cultural capital within social groups, which make these groups distinctive in how they might approach problems and look for solutions.

In science studies, heritage has a twofold operationalisation. First, a researcher’s heritage is located in the organisations where she was first socialised into scientific profession. Through the process of socialisation, doctoral researchers learn about the rules, norms and expectations associated with doing scientific research (Knorr-Cetina, 1999). These norms are localised in organisations and countries. Second, heritage refers to the broad shared culture of social groups, which, most importantly, includes language. Second generation migrant researchers and entrepreneurs maintain their parents’ country of origin heritage and are able to act as mediators in the global innovation system (Khadria, 1999). Such broad understanding of heritage may also have an effect on the dynamics of international collaboration.

In the case of Russia, the country has developed a peculiar research and innovation system during the Soviet period, and even over 20 years after the USSR broke down, the research system is heavily path-dependent (Karaulova et al., 2016). At the same time, throughout the 1990s, Russia experienced high rates of ‘brain drain’, especially of the best recognised scientists in physics and mathematics (Graham and Dezhina, 2008). As of the mid-2000s onward, the Russian state set out the course towards internationalisation of domestic research, with the purpose to link the country with the global scientific community and benefit from knowledge exchange.

The set of related studies that analyse similar dynamics have so far focused mostly on the role of Chinese overseas diaspora in gatekeeping and/or mediating international collaboration (Freeman and Huang, 2015; Jin et al., 2007). This research has suggested some avenues of analysis, but has not discussed the implications of what the structural differences in international collaboration dynamics mean for how we should interpret science indicators.

Methodology

In our previously published research, we developed a method to identify the national heritage of authors based on the morphology of their surnames (Karaulova et al., 2019). By employing this approach, we infer Russian heritage from author surnames in internationally co-authored publications. Surname data has been used in bibliometric analyses to determine contribution of recognisable ethnic groups to the development of particular discipline (Kissin, 2011), to determine effects of inter-ethnic collaboration on quality of publications (Freeman and Huang, 2014), or to highlight the contribution of ethnic and gender minorities (Lewison, 2001). Taking Russia as a case study of this research has another benefit: in a country that was internationally isolated for the large part of the 20th century, geographical approximation of 'Russian' surnames is consistent with the actual population, i.e. most Russians still live in Russia (Revazov et al., 1986).

We take advantage of the fact that Russian surnames have persistent morphological regularities, and the majority of them can be identified from a small set of specific suffixes. Combined with first name data, this procedure has very high rates of recall and precision. By using the author name data, we can distinguish the heritage of a researcher from their work address and therefore analyse the extent to which Russian scientists in Russia collaborate with Russian scientists abroad, and what such international collaborations might mean.

We analyse publications indexed in the Web of Science that have at least one author with an address in Russia. The dataset includes 709,360 publications, the date range is 1995-2015. All disciplines, languages and document types are included in the data. Within the dataset 82.2% of publications have a co-author and 34.1% of those collaborated papers have a co-author with an address outside of Russia.

Initial Findings

Using the surname-based lexicological method, each author in the dataset is marked either as Russian heritage or non-Russian heritage. After applying the two-step Russian heritage identification procedure, we classified 95,7% of the records with the address in Russia as "Russian heritage authors", which broadly corresponds with our previous estimates that the Russian science system does not employ many non-Russian researchers (Karaulova et al., 2019).

The findings from a small pilot study of a random sample of records published in 2015 showcase that the method outlined above can be used to address our research objectives. In the random sample, we found a significant bias in internationally collaborating research: only 18% of the internationally co-authored publications were co-authored by authors in Russia and by non-Russian authors abroad, whilst the vast majority of these papers had at least one Russian heritage author based in Russia, one Russian heritage author based abroad and one non-Russian heritage author based abroad, which possibly suggests a mediation function.

Countries that have extensive international collaboration networks and are the 'core' of science globalisation, such as the USA (Wagner and Leydesdorff, 2005), have lower rates of overseas diaspora involvement in the structure of collaboration networks with Russia. While the share of research papers collaborated with the participation of Russian heritage authors reached 40% for major international partners of Russia, the results are more telling for minor partners. Countries that have relatively strong science base, but do not have traditionally close links with Russia, such as Portugal, Belgium or Australia, demonstrate very high level of overseas diaspora involvement in the share of publications co-authored with Russian scientists.

Discussion and Conclusions

If a significant share of international collaborations of a national research system occurs with researchers previously affiliated with this system, internationally co-authored publications are therefore only 'inter-national' on a formal inter-organisational level, but in fact occur between co-authors that share academic upbringing and culture. This finding contributes to the evidence that stresses more complex nature of scientific collaboration (Bozeman and Corley, 2004) and may have fundamental implications on the use of international collaboration indicator and on science policy decisions.

We found that in a significant minority of internationally collaborated papers, co-authors are likely to have the same origin. In other words, we observe an overestimation in the international collaboration indicator. This inherent bias in the established international collaboration indicator may overestimate the impact of international collaboration on periphery countries in comparison with its impact on advanced core countries. This paper makes a call for revision and further detalisation of the indicator that is sensitive to unequal science development dynamics.

When bibliometric tools are used to measure international collaboration and cooperation, invariably, assumptions are made about the social reality of these tools. Globally, the findings of this study are valid for national science policy of countries that rely on international collaboration networks to foster the development of domestic science and technology through knowledge transfer and spillovers.

Abstract

This research-in-progress investigates whether there are differences in terms of traditional citation impact and broader impact (Mendeley, Usage and Social Media) for researchers with different social variables such as age, gender and academic position. To do this, 30,003 journal articles in *Web of Science* from 2011-2017 with Norwegian *first authors* that can be identified as *persons* in two other Norwegian national databases, are selected as our data sample. Among a total of 14,204 identifiable researchers as the first authors, 7,767 (55%) are men and 6,437 (45%) women. Percentile-based indicators of four different impacts are compared among different researcher cohorts. The preliminary results show that although there is a consistent male dominance in traditional citation impact, the dominance is less present in the younger cohorts where females are also better represented. Female researchers score relatively higher on broader impact indicators than on traditional citation impact indicators, sometimes clearly exceeding their male colleagues. The differences already revealed will be further studied by including academic position as another social variable, to better understand the distinct impact characteristics according to age and gender, and to provide new insights for funding and evaluation policy.

Introduction

In an earlier study (Zhang & Sivertsen, 2017), we found that while the average publication productivity of researchers increases with seniority, average citation impact does not. Citation impact was the highest for post-docs and in general for young researchers in their 30's in our study of 17,750 researchers in Norway. Men were on the average more productive than women, but the difference in citation impact was smaller. Previous studies (e.g., van den Besselaar & Sandström. 2016; Larivière & Costas (2016); Barrios et al., 2013; Aksnes et al., 2011) had found that productivity and citation impact are correlated, which might imply that funding should primarily follow productivity (Sandström & van den Besselaar (2016) or that individuals are best assessed by qualitative peer review to avoid strengthening the accumulative advantages of senior researchers (Larivière & Costas, 2016). We instead concluded that the opportunities to be productive within WoS varies with social variables, and that lower productivity among women and among researchers in early careers needs not inhibit high citation impact.

We reached this conclusion by using different methods. While the previous studies were based on author name disambiguation within data from WoS, we were able to study persons, not just authors. We matched WoS data with two other data sources at a national level where the author names and addresses in the publications could be linked to real persons and institutions. From these other data sources, we also knew the age, gender and academic position of the researchers.

In this new study, we extend the perspective by looking at the *broader impact* of the publications of the same kind of sample of researchers. We extend our datasets to: 1) include all Norwegian researchers when they appear as first authors in journal articles in Web of Science (WoS, 2011-2017); 2) add the altmetric data for each article under study from *PlumX Metrics* created by Plum Analytics. As research-in-progress, we will present here the results from using the social variables *age* and *gender*.

We define the term *broader impact* very narrowly to reflect the limitations of our data sources (see also the data and methods section below):

- The publications we study need to be scientific and indexed in WoS. We measure their scientific impact on the basis of their citations within WoS.
- The publications need to be matched to *PlumX Metrics* data with their DOI (Digital Object Identifier).
- Selected statistics from *PlumX Metrics* are aggregated into three major broader impact indicators named *Mendeley, Usage* and *SocialMedia* (explained in the methods section below).

The term *broader impact* is thereby used for possible traces of impact that the scientific publications might have beyond becoming references in new scientific publications, as measured by citations within WoS. Our three broader impact indicators, Mendeley, Usage and SocialMedia, are meant to reflect different types of influence beyond scientific impact. However, although the three indicators represent different kinds of influences from usefulness in research via academic readership to broader attention and discussion in social media, it is still important to acknowledge their limitations regarding what is usually understood as the *broader* or *societal* impact of research.

Broader impact is usually defined much more broadly, e.g. by the National Science Foundation of the USA as ‘the potential to benefit society and contribute to the achievement of specific, desired societal outcomes’.[1] With another word and a similar definition, the Research Excellence Framework of the UK defines *societal impact* as ‘an effect on, change or benefit to the economy, society, culture, public policy or services, health, the environment or quality of life, beyond academia.”[2] In our view, our three broader impact indicators, and in general so-called *altmetrics* (Wilsdon et al., 2017), can only in a very limited way support such broad definitions of broader or societal impact with relevant data. The reason is that these indicators are based on the influence of *scientific publications*. Altmetrics essentially measures readership, or the direct influence, of these publications (Haustein, 2014). However, the interaction between research and society is seldom mediated directly through scientific publications, and not even through the written words of scientists (Gibbons et al., 1994). Such interactions need to be studied with the use of data sources reaching beyond written communication (Bornmann, 2013). However, indicators of online views, downloads, readership, and social media attention can supplement traditional bibliometrics for the understanding and evaluation of research activities (Bornmann, 2014).

Data and methods

Our study depends on the matching of four data sources at the individual article and author/researcher level:

1. *National Citation Report for Norway (NCR, 1981-2017)*, a data set provided by Clarivate Analytics with a representation of all articles in Web of Science with minimum one address in Norway, and their accumulated citation counts.
2. *The Norwegian Science Index (NSI)*, a subset of the Current Research Information System in Norway (Cristin), with complete coverage since 2010 of all peer-reviewed scientific and scholarly publication outputs from Norwegian institutions, including books, edited volumes, and conference series (Sivertsen & Larsen, 2012). This database is used to match data sources 1 and 3, and also to match data sources 1 and 4 with DOIs not registered in Web of Science.
3. *The Norwegian Research Personnel Register (NRPR)*, which has been updated since 1977 for all researchers at public research institutions in Norway, including age, gender, educational background, affiliations and positions.
4. *The PlumX Metrics*, which provides insights into the ways people interact with individual pieces of research output in the online environment. It categorizes metrics into 5 separate categories: Citations, Usage, Captures, Mentions, and Social Media.

As a first step, we selected 30,003 journal articles in *NCR* from 2011-2017 by using four criteria: Firstly, they were covered by NCR. Secondly, at least one of the authors was affiliated with one of Norway's four largest universities (Oslo, Bergen, Trondheim, Tromsø). The time and resources to perform research are equal among these four institutions. Thirdly, the publications could be linked to *PlumX Metrics* through their DOI number in NCR in order to obtain their broader impact information. The broader impact data for each publication was retrieved from *PlumX Metrics* by the end of August 2018. The fourth criterium was to include only publications with Norwegian *first authors* that can be identified as *persons* in NSI and NRPR. We selected only first author publications for the same reason as in Thelwall (2018a; 2018b): First authors most often perform most of the research. Most of the articles in our data are multi-authored with a representation of both men and women. To study gender differences in impact more distinctly, we chose to include only those publications where the persons we study are first authors.

The four selection criteria resulted in a total of 14,204 identifiable persons as the first authors. Among these, 7,767 (55%) are men and 6,437 (45%) and women. The persons are placed in five-year age cohorts according to their age in the publication year. The first and last cohorts are extended to include a few outliers. Table 1 shows how they are distributed by major area of research, gender and age cohorts. The classification of persons in major areas of research was done according to the journal-based classification of publications in NSI, which consists of four major areas and 82 subfields. Persons were placed in only one major area each. If in doubt, we also consulted their organizational affiliations (e.g. a department of sociology would place the researcher in the category Social Sciences).

Table 1. Gender and age cohort distribution in four major area of research

	Health Sciences		Natural Sciences and Engineering		Social Sciences		Humanities	
Age cohort	Women	Men	Women	Men	Women	Men	Women	Men
21-30	662	445	573	1082	33	36	16	9
31-35	830	582	580	1045	65	60	15	19
36-40	775	632	302	675	61	69	30	27
41-45	649	472	187	373	64	57	23	24
46-50	392	306	91	202	37	52	16	22
51-55	377	280	45	157	40	41	12	15
56-60	249	222	35	137	28	52	13	18
61-65	120	154	7	92	19	33	8	9
66+	61	189	5	132	13	35	4	12
Totals	4115	3282	1825	3895	360	435	137	155
Gender balance	56 %	44 %	32 %	68 %	45 %	55 %	47 %	53 %

After testing the *PlumX Metrics* data with regard to reliability and validity for meaningful statistical analysis (several indicators have low frequencies), we selected three different metrics by aggregating specific indicators from *PlumX Metrics*:

1. The 'Mendeley' indicator is based on the number of readers a paper has had in Mendeley.
2. The 'Usage' indicator represents the frequency of the users' abstract view or full-text view. The two frequencies are summed up.
3. The 'SocialMedia' indicator represents the number of times a publication is referred to in Twitter and Facebook. The two frequencies are summed up.

We could compare these three *broader impact* indicators with a fourth indicator of *scientific impact* that could be readily retrieved from the NCR database: Web of Science citations, normalized by WoS subject category and year, and expressed as percentiles after ranking the articles from the most cited to the least cited. The percentile indicator in NCR compares to all articles in the world in the same subfield and year. We adopted the same *percentile* method for the indicators based on PlumX data. Here, we could only measure the percentiles within our data, a subset of Norwegian publications covered by our matched data sources. We normalized by the year and major area of research of the *publication,* using the NSI classification with four major areas and 82 subfields mentioned above. Within each major area of research, we selected and tagged the top 10% papers according to impact in each of the three categories 'Mendeley', 'Usage' and 'SocialMedia'.

For all four indicators, we measure a *cohort's share* in the *top 10 percent high impact publications* (according to the four indicators) divided by the *same cohort's general share in all publications*. Values above, below or equal to 1 will therefore show whether the cohort in focus is over, below or equal to the impact performance that can be expected in general among its peers. With the term 'cohorts', we refer to any selected groups of researchers by the options that are shown in table 1. Since the persons in our data are placed in one group only, the groups may also be aggregated without duplicating.

Results

The aim of this research-in-progress paper is to present the most immediately interesting results that inspires our further investigations. As seen in Figure 1, the impact of female researchers is relatively higher as we move from traditional citation impact to impact in Mendeley. This is as expected from the results in Thelwall (2018a). One of the possible reasons may be that female researchers are more oriented towards the educational relevance of their research, which might attract more student audiences (Thelwall, 2018b).

As we look beyond traditional citation impact and Mendeley in our study, we observe, to our surprise, that there is an even stronger tendency among female researchers to have relatively higher impact on usage (online views) and mentions of their papers in social media. The difference by gender is particularly large on the usage indicator. Our further investigation will seek explanations for this by going deeper into field-specific patterns. We will also include the academic position of the researchers as a variable.

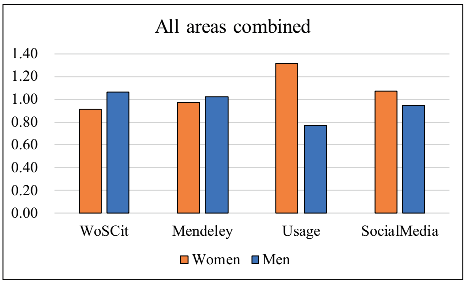

Figure 1. Gender and impact*

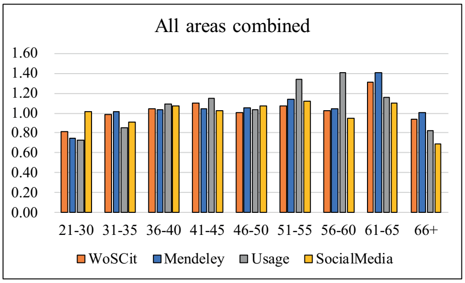

Figure 2. Age and impact

* All areas combined. The vertical axis indicates the shares in top 10% high impact publications compared to (divided by) the general shares in all publications. Shares have been calculated for all according cohorts for each impact indicator. The same applies for Figures 2-6.

Our aggregated results regarding the age of the researchers are presented in Figure 2. Here, the general patterns seem to imply that impact in research by three of the indicators, citation impact, Mendeley impact, and usage impact, comes with age. Impact in social media may be high also among younger researchers. We will investigate further why the four impact indicators have very deviating results in some age cohorts (researchers younger than 31 or older than 50).

Figure 3 shows the most impressive result of our preliminary investigations. Why are the publications from female first authors consistently more attracted by online views (full text or abstracts) than publications by male first authors? And why are the older female researchers, and not the older male researchers, so clearly more outstanding than any other cohorts by this indicator? Again, we need to get down to research fields, academic positions, and possible purposes and uses of research, to explain these impressive findings.

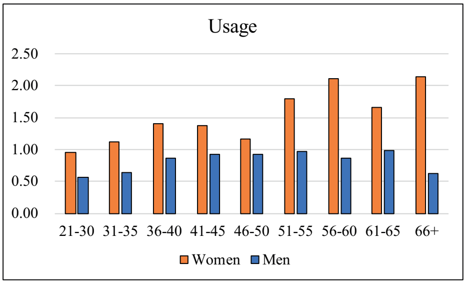

Figure 3. Age, gender and usage impact

Preliminary conclusion and further research

Although there is a consistent male dominance in traditional citation impact, the dominance is less present in the younger cohorts where females are also better represented. Female researchers score relatively higher on broader impact indicators than on traditional citation impact indicators, exceeding their male colleagues most clearly by usage impact. The preliminary results already provide evidences that it is worthwhile looking at the performance of young female researchers before all the funding is prioritized towards older male professors. In our further research, we will study each major area of research and also go down to subfields to find possible explanations for these impressive findings. We will look carefully at the publications with the highest impact by all four indicators. We know already that these publications are not the same across the four indicators. We will characterize what type of research and research purposes that have the highest impact by different measures. We will also study the two social variables, gender and age, more closely, and we will add academic position as a third social variable.

Assessing the Impact of a Highly-Cited Paper

Paul Alkemade

p.f.a.alkemade@tudelft.nl
Applied Physics, Lorentzweg 1, 2628 CJ, Delft University of Technology, Delft, The Netherlands

Abstract

The use of citation indicators to gauge impact in science has increased significantly in the last decades. Yet, in the normal sense of the word, the impact of a scientific paper is still largely elusive. This work presents the results of full textual analysis of all citations of a single highly-cited paper. For this purpose, a reference impact score *RIS* is defined, which is derived from the context and content of the citations. First results suggest that the *RIS* reflects the impact of the cited paper on the research in its citing articles. Low-*RIS* citations in particular are often perfunctory and redundant, whereas high-*RIS* citations reveal regularities that might be related to impact.

Introduction

A cornerstone of science is peer review. Journal editors ask reviewers to estimate among others the expected impact of a submitted manuscript within or beyond its field of research. But reviewers rarely assess the *actual* impact of papers. This activity is usually handled many years later by bibliometricians, who can apply various statistical methods for the assessment of impact. The most known method is citation counting. The interest nowadays in the role of citations in science, scientific achievements, and science policies is large and to some degree controversial, see *e.g.* the San Francisco Declaration (2012). Some bibliometricians hold the normative view that citation counts correlate well with the impact of scientific papers, authors, and journals. Others, in contrast, adhere to the social-constructivist view that there is a plethora of motives for citing or not citing and argue that also external factors influence citing. Read Tahamtan (2018) for a recent discussion of these opposing views.

Some assume that the impact of a paper can be best derived from textual analysis of the context and content of citations. In the 1970s, Murugesan (1978) proposed a method to categorise citations in five opposing dichotomies, such as 'conceptual versus operational' and 'confirmative versus negational'. Alternative schemes have been explored as well, usually to limited data sets because textual citation analysis is laborious and cannot be automated easily. For an overview, read Ding (2014) or Bornmann (2012). An example of a rare *normative* study on citation context and content is by Maricic (1998), who analysed citations to a few hundred papers from one institute and ranked the citations according to location, frequency, and importance.

In this work I present the results of a textual analysis of 145 citations in 102 articles to a single paper by Abbas (2014) in a leading journal in Nanoscience and -technology, the field of my expertise. The citing articles[1] in the period of January 2014 to December 2018 are collected via Web of Science and Google Scholar. In particular, I introduce an appraisal or scoring scheme for the impact of the cited paper on each citing article, based on citation characteristics that have been identified in the literature as likely being related to the impact of publications. This score, called the *reference impact score* (*RIS*), quantifies and combines these characteristics into a single number. Although the presented analysis is based upon a subjective interpretation by one person, I will hypothesize that, after harmonization and validation, the *RIS* can reveal elements of the impact of publications on the advancement of science that are otherwise barely discernible.

[1] Here, the cited work is called 'a paper' and the citing work 'an article'. 'A reference' is an item in the reference list of an article.

The reference impact score

The *RIS* method assigns a value, a reference impact score *RIS*, to one reference in a citing article. Table 1 gives an example of a *RIS* scoring scheme for four characteristics of a citation, related to its context and content. The choices for scores are personal, but they have I hope a more general usefulness, at least in my own discipline. First of all, the *RIS* depends on the location of the citation in the article. Citations in the introduction section are part of a sketch of the relevant research field. Few criteria exist for citing in introductions and the number of citations in introductions is usually high (Boyack 2018). Hence, a rather low score of 2 points is given to citations in the introduction. I assume that the conclusion section is the climax of an article. The intermediate sections describe the actions, observations, and interpretations that provide evidence for the conclusions. Therefore, the score gradually rises to 7 points for citations in the conclusion section. The exception are citations that describe the motive or aim of the article, most often at the end of the introduction, but logically linked to the conclusion. Their scoring is 5 points. Review articles have a completely different structure and, therefore, a general score of 3 is giving, independent of the citation's location.

Table 1. Example of a scoring scheme for citations. The score depends on the context (categories I, III and IV) and function (category II) of the citations in the narrative of a citing article. The reference impact score *RIS* is the highest citation score of a citing article plus bonuses for additional citations. Review articles in category I get score 3. Category II has double weight *w*.

Category	*Label*	*Meaning*	*Score*[2]
I.	i	introduction section: background sketch	2 / 3
'Location'	q	introduction section: aim or motive	5 / 3
(*w*=1)	m	methods section	3 / 3
	r	results section	4 / 3
	rd	results & discussion section	5 / 3
	d	discussion section	6 / 3
	c	conclusion & summary section	7 / 3
II.	o	using a graphical object	1
'Function'	i	introducing the reader	2
(*w*=2)	m	referring to the method	3
	s	stating an opinion	4
	r	presenting a result of the paper	5
	d	discussing a topic in the paper	6
III.	1	sentence with a single reference	6
'Grouping'	1-2	sentence with one group of multiple references	4
(*w*=1)	2-1	sentence with multiple groups of single references	4
	2-2	sentence with multiple groups of multiple references	2
IV.	few	< 41 (<120 for reviews)	3
'# of refs.'	average	41...50 (121...200 for reviews)	2
(*w*=1)	many	>50 (>200 for reviews)	1
'Reference impact score'		*RIS* = highest citation score	var.
		+ bonus for 2nd highest-scoring citation (if present)	5
		+ bonus for 3rd highest-scoring citation (if present)	3
		+ bonuses for all other citations (if present)	2

Each citation has a function (category II) in the narrative of the article, sometimes important sometimes not. Using a graphical unit from one of the cited paper's figures is rarely important, hence 1 point. Introducing a reader to the research field is, as argued above, useful but most citations are not very important. Also the score for function rises gradually, up to 6 points for a citation that discusses a particular topic. Assigning scores for function is rather difficult,

[2] The first score is for experimental and theoretical articles, the second for reviews.

because it depends both on the interpretation of the content of the citation and on the value system held in the specific discipline. Scoring of the grouping of the citation between other citations in the sentence (category III) is simpler. A citation like '*One can use the method by Young et al. {11}*' has more importance (6 points) than one with joining citations like *'One can use the Young method {11-14}'* (4 points). Also multiple groups of citations, like *'One can use the method by Young {11} or the slow-electron method {15}'*, receive 4 points. If the citation is grouped with other citations and there are multiple citation groups, *e.g. 'One can use the Young method {11-14} or the slow-electron method {15-17}'*, the score for reference {11} is 2 points. The importance of a cited paper is relatively low if the reference list is long. Therefore, the total number of references is another category (IV). Three different scores are possible here. In this example, the bounds are such that each class comprises one third of the citing articles.

The scores of categories I-IV are combined with weights into a total citation score. A paper that is cited multiple times in an article is obviously more important than one that is cited only once. One could add the individual scores, but repeating a statement that was already true in *e.g.* the introduction, does not make it more true. Therefore, the encompassing reference impact score *RIS* of a reference in an article is defined as the score of its highest scoring citation plus bonuses for possible additional citations. For instance, if the first citation is characterized by *'i m 2-1 few'*, the score is 2+2x3+4+3=15. If the second citation is *'i d 2-2 few'*, the score is 2+2x6+2 +3=19. Hence, the reference impact score *RIS* becomes 19+5=24.

Results

Table 2a presents as example six citations in four articles. In general, a citation is a phrase, a full sentence, or a few sentences. Interpretation of the content of the sentence(s) determines which parts belong to the citation; they are printed in black or red in Table 2a. Fragments that are not part of the citation are grey. The citation is red if it negates an observation, interpretation, or conclusion in the cited paper. The analysis for these six citations is in Table 2b. Columns 3–12 give the corresponding dichotomous Murugesan and Moravcsik (MM) classification. Column 13 lists the location of the citation, the meaning of the labels are in Table 1. Column 14 is the interpreted function of the citation. Column 15 denotes the grouping of the citation

Table 2a. Selection of citations of Abbas (2014) by (1) Mondal (2014); (2) Fox (2015); (3) Rivera (2016); and (4a-c) Stanford (2017). Black and red fragments are citations, grey not. The red citations are in variance with Abbas (2014).

No.	*Citation*
1	Thus, in order to make it a material of same caliber as silicon, engineering of the band gap of graphene becomes essential [7-11,12].
2	For example, graphene nanoribbons with dimensions below 10 nm have been fabricated by this method [32,33,34]. This ribbon width may be useful in order to exploit the properties of quantum confinement. However, the nanoribbons must also have well-defined edge orientations and good crystallinity. Whether this can be achieved by He^+ milling has not yet been investigated due to a lack of understanding and control of the beam-sample interaction.
3	In the high-confinement regime, the radiation into plasmons is dominant and can be harvested as far-field light through suitable outcoupling techniques such as gratings and nanoantennas [39, 44,45,46].
4a	Abbas et al. have used He patterning to create arrays of 5nm GNRs [133] as shown in Fig. 22(a). However, Raman spectra shown in Fig. 22(b) of the GNRs indicate a significant amount defects in the arrays from the patterning process that results in a rise of the D/G peak ratio, since the D peak is forbidden in defect-free graphene. This could ultimately limit the application of He-milled GNRs for high performance FET applications.
4b	*(Copied figure)* [133].
4c	*(Table element of graphene processing methods)* [133].

Table 2b. Citation classification and scoring. Column 2: E=experimental, T=theoretical, R=review. Columns 3–12 refer to the MM classification of Murugesan (1978); columns 13–16 refer to the *RIS* scheme of Table 1; column 17 is the topic of the citation (a=application, f=fabrication, p=physics). Column 18 is the citation score, derived from columns 13 to 16, and column 19 is the reference impact score *RIS*. Note that not all boxes are filled.

1	E	1			1	1		1			1	i	d	1-2	60	a	11	**11**
2	E		1		1	1			1		1	q	d	1-2	48	p	23	**23**
3	T		1		1			1			1	d	i	1-2	50	a	16	**16**
4a	R								1			-	d	1	160	f	24	**32**
4b								1				-	r	1	160	f	20	
4c								1				-	m	2-2	160	f	14	

and column 16 the total number of references in the citing article. Column 17 gives the topic of the citation (there is no scoring for the topic); 'f' means the fabrication method in the cited paper, an 'a' the application, and a 'p' means a physical phenomenon. The numbers in the final column 19 are the reference impact scores *RIS*, based on columns 13–16 according to the scoring and weighting scheme of Table 1. Here, the article by Stanford (2017) has three citations to Abbas (2014). For this article, *RIS*=(4+2x6+6+2)+5+3=32.

Table 3 presents the results of the dichotomous MM classification, together with the original results by Murugesan (1978). Because reviews have a different structure and function, only the experimental and theoretical articles are considered here. Dichotomous classification is often difficult, because there is rarely a sharp boundary between the class pairs. A slightly different formulation could have shifted a citation into the opposing class. Nevertheless, I deliberately did not use 'not indexed', because the boundary between classifiable and non-classifiable is even vaguer. Theoretical articles are evolutionary with regard to experimental articles –one follows from the other and vice versa– and at the same time juxtapositional –because a theoretical approach is an alternative to an experimental one. Therefore, this dichotomy has not been indexed for theoretical articles. Review articles, for which only the confirmative-negational dichotomy is used, are not included in Table 3.

Table 3. Citation characteristics for the MM classification. First row: 3500 citations in physics journals around 1975 by Murugesan (1978). Second row: 99 citations to Abbas (2014) in this work. *r/a* = mean number of references per article. Numbers in column 3 and later are percentages.

year	*r/a*	*conc.*	*oper.*	*n.i.*	*orga.*	*perf.*	*n.i.*	*evol.*	*juxt.*	*n.i.*	*conf.*	*nega.*	*n.i*	*indi.*	*redu.*	*n.i.*	
1975	16	27	64	9	39	60	1	46	51	3	89	9	2	<66	34	?	%
2014	46	10	90	0	18	82	0	32	41	27	86	14	0	7	93	0	%

An unmistakable difference between the 1975 and 2014 analyses is the tripling of the number of references per article (*r/a*). Boyack (2018) found almost a doubling between 2000 and 2015, up to 39 references per article. Also the percentages of operational, perfunctory (=of short duration), and redundant citations are now much higher. This rise might be related to the increase in references per article.

Table 4. Summary of the *RIS* analysis of 101 experimental, theoretical, and review articles, that cite Abbas (2014). a) gives citations counts for categories I to III. b) gives topics ('res'=rest); and c) gives citing article counts per year (2014-18) for the ~50% lowest and highest *RIS* articles.

high RIS	5	11	15	13	6	50
All	12	24	23	24	19	102

Table 4 summarizes the statistics of the *RIS* analysis. There are 72 citations in 53 experimental articles. In all theoretical articles but one, there are only single citations, whereas review articles have on average almost two citations per reference. Most citations appear in the introduction and the second most in the discussion section. This characteristic is stronger for experimental than for theoretical citations. Similarly, the most abundant function of a citation is to introduce the reader, then to discuss an issue. The introductory function is very strong for theoretical citations. The function of review citations exhibits a much wider spectrum. Grouping of citations is common in experimental and theoretical articles, but not in review articles.

In Figure 1 the *RIS* of the articles is shown as function of time delay between the publication dates of the cited paper and its citing articles. Different symbols and colours indicate different citation characteristics.

Discussion and conclusion

Although the number of analysed cited papers in this work is absolutely low –unity– the number of citing articles is rather high, ~100. This moderately high number allows for statistical analysis of differences in citing behaviour between articles. I have assigned a reference impact score (*RIS*) to the context and content of the citations. My hypothesis is, that authors of articles with a higher *RIS* are more influenced by the cited paper than others. I found indications that this is true for same-type (namely experimental) articles. Ignoring self-citations, the first high-*RIS* articles appeared with a delay of 11 months, see Figure 1a and Table 4c. After four years, the experimental high-*RIS* articles started to dwindle. Citing review articles appeared with a similar delay, probably due to a long production process. Figure 1a shows that most organic (+), negative (purple rim), and indispensable (+) citing articles have a high *RIS*. Figure 1b gives a mixed picture: organic citing theoretical articles have a low *RIS*, whereas negative citing reviews have a high *RIS*. These trends suggest that the *RIS* is indeed a meaningful indicator for the impact of cited papers on the research activities of citing authors. Besides, the impact on the majority of the citing authors seems low: perfunctory and redundant citations dominate, impairing the validity of citation counting as a measure of quality.

This analysis of all citations to one highly-cited paper by one interpreter has limited general validity. Hopefully, the attribution of scores to the various characteristics of citations (Table 2) can be harmonised within a discipline of science, thus with sufficient consensus on the relative importance of the characteristics. Furthermore, the categorisation of citations (Table 3) must be

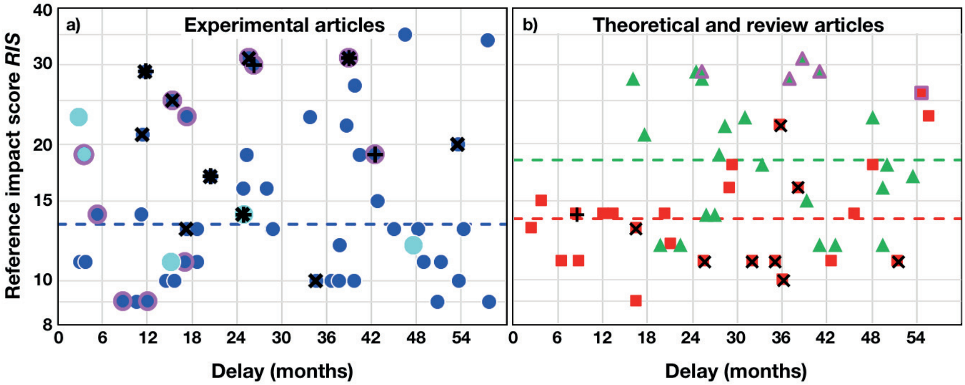

Figure 1. Reference impact score *RIS* versus time delay between the publication of cited and citing works. a) experimental articles (light-blue: self-references). b) theoretical (red) and review (green) articles. Purple-rim: negational; +: indispensable; x: organic. Dashed lines are medians, separating the low and high *RIS* articles. The vertical scale is plotted logarithmically.

validated such that categorisations by different specialists will be sufficiently correlated. Peers play a crucial role in the publication of scientific papers and with their expertise they could also appraise citations and uncover impact. Often, however, they have limited interest in 'old' papers, their expertise concerns a small field of science, and –not unimportantly– they have limited time. Computational linguistics, *e.g.* along the lines of Taskin (2018), is a very different approach to textual citation appraisal. Maybe, a clever combination of peer appraisal and computational linguistics can reveal impact in the normal sense of the word.

Abstract

Science mapping using document networks is based on the assumption that scientific papers are indivisible units with unique links to neighbour documents. Research on proximity in co-citation analysis and the study of lexical properties of sections and citation contexts indicate that this assumption is questionable. Moreover, the meaning of words and co-words depends on the context in which they appear. This study proposes the use of a neural network architecture for word and paragraph embeddings (Doc2Vec) for the measurement of similarity among those smaller units of analysis. It is shown that paragraphs in the 'Introduction' and the 'Discussion' section are more similar to the abstract, that the similarity among paragraphs is related to -but not linearly- the distance between the paragraphs. The 'Methodology' section is least similar to the other sections. Abstracts of citing-cited documents are more similar than random pairs and the context in which a reference appears is most similar to the abstract of the cited document. This novel approach with higher granularity can be used for bibliometric aided retrieval and to assist in measuring interdisciplinarity through the application of network-based centrality measures.

Introduction

Document networks with weighted edges based on similarities using either citation links (Small, 1994), lexical similarity (Wang & Koopman, 2017) or combinations (eg. Ahlgren & Colliander, 2009; Thijs & Glänzel, 2018) and unweighted approaches using direct citations links (eg. Boyack, 2017) have been used for science mapping exercises. In these studies, documents were assumed to be indivisible units, each with unique links to neighbouring nodes holding a single value indicating the strength of the similarity in the case of a weighted variant. Then, these networks were subject of community detection or clustering approaches which resulted in hard clustering assigning documents to single groups or clusters of papers. However, it becomes more and more clear that the basic underlying assumption in these models is questionable. A document is often not to be reduced to such a single point or entry in the knowledge space.

A recent paper (Thijs & Glänzel, 2018) using full texts from the journal Scientometrics identified papers that shifted easily from one cluster to another after slight changes in the weighting parameter in the combined citation-lexical approach. A set of papers on institutional performance was split into two groups with the first focusing on university ranking and name disambiguation problems associated with this topic and the latter one related to institutional performance in social sciences. The first group was merged into the topic of '*Research Assessment*' while the latter one becomes part of the set of papers labelled as '*Field and Regional Studies*'. Both these clusters were not specifically labelled as dealing with institutional research. It is impossible to indicate whether one or the other grouping was better. Both had similar quality scores.

A similar observation was made by Boyack (2017) when he compared local cluster solutions in the field of Astronomy with the topics identified in his global science map. Several typical Astronomy topics from the global map did contain publications that were not in the initial data set due to their lack of compliance with the retrieval strategy. Other papers from the initial set were to be found in topics that were clearly not primarily on Astronomy. These papers had a large portion of their links to non-Astro papers. Working on the same data set, I identified

papers studying the effect of absence of gravity on the growth of plants connecting both agriculture with astronomy (see Kiss et al., 2014 as an example).
This leads to the proposition that a more fine-grained approach should be applied in science mapping where the unit is no longer the document but at lower levels like sections, paragraphs or even sentences. This has already been alluded to by several studies using an enhanced co-citation analysis which incorporates also the proximity of the cited references. Several studies indicate the co-cited publications are more similar if the distance of their in-text citation is smaller (see Gipp & Beel, 2009). Complementary to these co-citation-based findings, others have reported different lexical properties of the subsequent sections in scientific papers. Bertin et al. (2016) reported different use of verbs and rhetorical structures surrounding references across different sections.

Other approaches that move away from the assumption of a document as an indivisible unit are probabilistic topic modelling techniques like LDA (Blei, 2012) where documents are linked to different topics with a weight relative to the probability that the topic is relevant to the document. With LDA, one has to set the number of topics prior to the analysis. Gal et al (2017) applied this technique to a set of publications from cardio-vascular research with an initial set of 200 topics where after expert validation only 166 remained relevant. Three issues remain unsolved when using topic modelling approaches. First, there is the initial decision on number of topics, next, the document remains the unit of analysis and the probability that a document is related to a particular topic is attributed to the document as a whole and finally, the use of bag-of-word approach in the learning phase neglects the differences in meaning a word can have depending on its context. Leydesdorff and Hellssten (2006) demonstrated how words and co-words retrieve their meaning from their presence in sentences and broader context.

This study proposes a new approach that moves the granularity towards smaller units of text namely the paragraphs in the different sections across a full paper and applies an analytical technique that tries to capture the meaning of words and phrases not only from its position relative to other words in its neighbourhood but also from the overall subject or topic covered by the paragraph. Vector word embeddings using neural networks architecture like GloVe (Pennington, Socher & Manning, 2014) and Word2Vec (Mikolov et al. 2013) are able to map words to a low dimensional space, with high performance. These word embeddings have however a single representation in the vector space neglecting the different meaning a word can have across different contexts. This is solved by adding an additional paragraph or document layer to the learned model which holds this context information (Quoc & Mikolov, 2014).

This study will use the Doc2Vec implementation in GenSim (Rehurek & Sojka, 2010) for the calculation of the word and paragraph embeddings and for the calculation of the similarities between low level units or fragments of text extracted from all PlosOne publications up to december 2018. As such, the current research is the first to apply these techniques at such a large scale with the following objectives. First, I'll try to measure the intra document similarity between the different paragraphs and between the paragraphs and the abstract. It is assumed that paragraphs close to each other have higher similarity, that paragraphs in the 'Introduction' and the 'Discussion'-section have higher similarity with the abstract and each other and that paragraphs in the 'Methodology' are least similar to all other paragraphs Next, the research focusses on documents linked through a citation. It is assumed that the context surrounding the reference is most similar to the content of the cited paper. In a last section of the study, the location of the reference in the citing document is mapped with the different paragraphs in the cited document in order to retrieve the cited information relevant to the citing document. The results from this study can have applications like bibliometric aided information retrieval or can assist in the identification of interdisciplinary research.

Data & Methodology

Data

This study uses publications from PlosOne downloaded from PubMed Central ftp://ftp.ncbi.nlm.nih.gov/pub/pmc. The downloaded set contains publications indexed until December 7th, 2018 and it holds 204,846 documents from 2006 onwards. The papers are provided in XML-format following the '*Journal Article Tagging Suite*' (JATS) standard. This schema divides the information in three main elements: <front>, <body> and <back> with an underlying structure of elements and attributes and complies with ANSI standard Z39.96-2012 (ANSI, 2012). This format, provided as an XML-schema, is then converted by the *Java Architecture for XML Binding* library (JAXB) into generated Java source code. This generated Java library serves then as a unmarshalling toolbox which can convert any XML-document compliant with the JATS-schema into a set of Java Objects (POJOs). This toolbox incorporates parts of the *CorpusHandling* library developed by *CyCorp* and available under Apache license (version 2.0) from GitHub (see https://github.com/cycorp/CorpusHandling/). Each XML-document is unmarshalled into a Java object and parsed in order to extract:

- Bibliographic information like title, article number, publication year
- Sections and paragraphs holding the actual text fragments of the paper
- In-text references identified by the <Xref>-tag
- References at the end of the paper

It is assumed that papers published in PlosOne adhere to the IMRaD structure (Introduction, Methodology, Results and Discussion) or a variation where the Methodology section is at the end of the paper (IRDaM) following the description of the distribution of sections across PlosOne publications (Bertin, et al. 2013). The title heading each section is used to classify the text fragment to one of the following classes:

I. Introduction; Background
II. Data; Material; Methodology; Design
III. Results
IV. Discussion; Summary; Conclusion
V. Other sections

Paragraphs are identified by XML-element tags <*sec*> and <*p*>, extracted and given a sequence number. Sentences are extracted and numbered within each paragraph. Figure 1 presents a paragraph from the first paper published in PlsOne (Harris et al, 2006).

> Early investigations focused on the role of neurons in subcortical stations and primary somatosensory cortex (SI) in coding low frequency "flutter" vibrations (below 50 Hz) **[1]–[3]**, while more recent work has emphasized the role of cortical areas "downstream" from SI, such as the second somatosensory cortex (SII) and regions of frontal cortex **[4]**, **[5]**. Which of these different areas, and which features of the neural activity within these areas, are essential components in forming the percept of a vibration? A series of psychophysical experiments with humans provided evidence that neural processes in SI contribute to frequency discriminations. In a task designed to resemble that performed by monkeys in the aforementioned neurophysiological studies, subjects compared two sequential vibrations and reported which had the higher frequency.

Figure 1. Text fragment taken from Harris et al (2006)
In-text references are marked in bold and underlined.

Next, in-text references (<*xref*>) are linked with the complete reference at the end of the paper and available identifiers like PMID, PMCID or DOI of cited papers are retrieved. This enables the linking of individual paragraphs to the cited paper. The position of the in-text reference with respect to extracted sentences in the paragraph is recorded. The in-text references in Figure 1 are marked in bold and underlined. The first <xref>-element is linked to the first three entries in the reference list at the end of the paper as it indicates the range between reference 1 and 3. The next two elements refer to the fourth and fifth entry. Each element in the text is replaced by the corresponding PMCID, PMID or DOI depending on the available data in the reference list.

Methodology

After extraction of the data from the XML-file, a set of processing steps is applied in order to obtain the vector word and paragraph embeddings. A pre-processing procedure as described in Thijs et al (2017) and Glänzel & Thijs (2017) based on the Stanford Natural Language Processing library (Chen & Manning, 2014) and the Lucene text search engine is used for the extraction of sentences, application of Part of Speech tagging, stemming, removal of stop-words and selection of noun phrases. Document identifiers like PMCID of the cited references are processed as noun phrases and retained at the original position within each sentence. Table 1 presents the results after pre-processing of the text fragment in figure 1. A list of all cited documents is added at the end of each paragraph as an additional 'sentence'. The choice to include the cited references in the final paragraph embeddings is not without consequences. It adds a bibliographic-coupling-like component to the embeddings.

Table 1. Parsed content of paragraph in Harris et al (2006) per section, paragraph and sentence.

The mathematical representation of the text fragments or paragraphs is based on vector representations built by a neural network architecture in an unsupervised machine learning algorithm. The applied methodology was first developed for distributed word embeddings at Google by Mikolov et al (2013) as a more complex substitute for simple vector-based representations like N-gram models. These embeddings are used to predict a word given the surrounding words in its context. The context is a sliding window with a fixed word length. The context is also applied to the identifiers of the cited references. Quoc & Mikolov (2014) extended the model for the inclusion of document or paragraph embeddings to outperform traditional bag-of-word approaches. Just like the original word embeddings model, the paragraph is represented by a vector in the same space as the words. It complements each fixed word length context used for the prediction of the words in the paragraph. The vector representation is unique for each paragraph and it is not shared among paragraphs and can be thought of as the representation of the topic the paragraph is dealing with.

The neural network used for training this model is a single layered architecture with a fixed dimensionality. In contrast to the LDA approach, these dimensions are not linked to topics and no external validation of the validity of the dimensions is required.

The Python implementation included in the Gensim library (Rehurek & Sojka, 2010) is used in this study. The algorithm is named '*Doc2Vec*' and takes the paragraph as a list of words as input with an additional tag identifying paragraph. This tuple is called a '*TaggedDocument*' in the library. The abstracts are tagged by the PMCID and paragraphs with tags containing the PMCID, section classification and sequence number of the paragraph. A cosine is calculated between the vector embeddings to measure the similarity between the text fragments.

The first set of analyses focusses on the intra-document similarity between paragraphs and abstract and among paragraphs. Figure 1 provides a schematic overview of the different analytical steps in this study. The intra-document similarity is indicated at the left-hand site. Within paper A, the abstract is compared with each paragraph and each paragraph with all subsequent paragraphs within the same section and across sections. The sequence number of the paragraphs are used to indicate the distance between the paragraphs in the text.

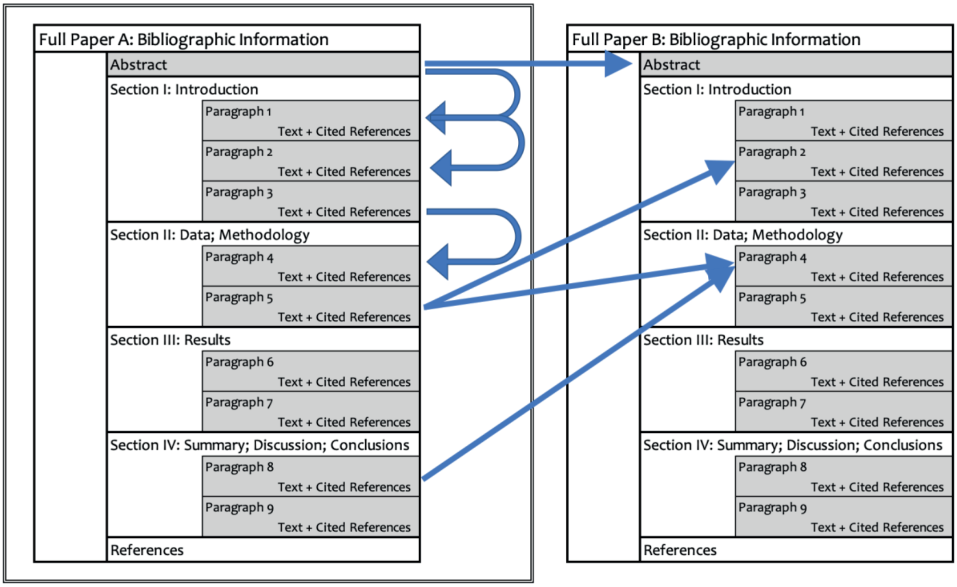

Figure 2. Schematic overview of the different comparisons.

The second set of analyses focusses on the similarity between citing and cited pairs of documents. In fig 2. there is a citation from paper A to paper B. The similarity of both abstracts in a citing-cited document pair is compared to the similarity in a randomly selected document pair. As the paragraph holding the in-text reference to the cited paper can be located, a next analysis compares the similarity between the citing paragraph and cited abstract and paragraphs across all sections within the citing-cited document pair.

Results

Descriptive Statistics

204,846 PlosOne publications have been downloaded and processed. 99% of these are recorded as '*research article*' in the Web of Science database and the remaining 1% as '*review*'. Table 2 provides the distribution of papers over publication years and the average number of paragraphs, together with the share of documents with the IMRaD sections in any order. Almost all documents have an introduction and discussion section.

Table 2. Descriptive statistics for downloaded PlosOne papers per year. Sections are classified based on the header of the section.

Publication Year	Publications	Average number of paragraphs	Introduction (I)	Methodology (II)	Results (III)	Discussion (IV)
2006	137	29.32	100.0%	99.3%	84.7%	100.0%
2007	1230	30.97	100.0%	98.5%	86.8%	99.4%
2008	2820	31.14	96.3%	95.7%	86.6%	96.0%
2009	4537	31.90	97.0%	96.3%	87.8%	96.8%
2010	6925	32.17	97.5%	96.9%	88.6%	97.3%
2011	14043	32.17	98.2%	97.3%	89.7%	97.9%
2012	24102	32.28	97.3%	96.0%	89.0%	97.0%
2013	32973	31.68	95.6%	93.4%	86.0%	95.3%
2014	30467	32.66	98.6%	96.1%	87.8%	98.4%
2015	28126	33.60	99.8%	96.8%	87.5%	99.6%
2016	22092	34.10	99.8%	96.7%	88.0%	99.6%
2017	20499	34.32	99.5%	96.2%	87.3%	99.2%
2018	16895	34.01	94.9%	91.2%	83.0%	94.6%
Total	**204846**	**32.92**	**97.9%**	**95.5%**	**87.3%**	**97.7%**

The publications contain on average 32.92 paragraphs and 3.86 different sections. This is below the values reported by Bertin et al (2013). This probably due to differences in parsing and extraction of the XML-elements. Subsections indicated by <sec>-elements as a child from another <sec>-element are not considered as separate sections and obtain their classification from their parent element. Section and paragraph elements without text as value were not considered as separate paragraphs.

The Neural Network Model

The final *Doc2Vec*-model is trained on 6.95 million text fragments from abstracts and paragraph texts. The neural network contains 400 nodes and training is done over ten iterations. Before training, a vocabulary was created with 3.90 million unique words. The total number of words included was 440 million. A sliding window of 7 words was used to establish the context for each word. It took about 15 hours to train this model on an average server requiring not more than 27Gb of RAM.

Intra-document similarity

First, the analysis focuses on intra-document similarity. Figure 3. shows the distribution of the cosine similarity of the abstract with distinct paragraphs across the four identified sections. The '*Introduction*' is most similar to the abstract, while the '*Methodology*' section is least similar. The inclusions of in-text references in the final paragraph embeddings and the absence of references in abstracts can act as a damping factor for the similarity between abstract and actual text fragments. However, the higher amount of references in the introduction and discussion (Bertin et al 2013) does not prevent the higher similarity between these sections and the abstract.

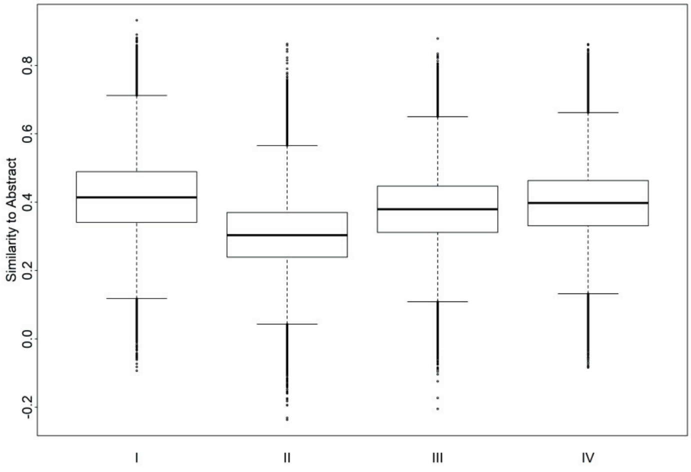

Figure 3. Distribution of similarity between Abstract and different sections in PlosOne papers.

Next, the similarity is calculated between paragraphs within sections and across section in each paper. The average similarities are presented in table 3. The intra-section similarity ranges from 0.32 for the '*Introduction*' to 0.29 for the '*Methodology*'. Looking at similarities across section, it can be observed that '*Introduction*' and '*Discussion*' are more similar, and '*Methodology*'-paragraphs are least similar to paragraphs in other sections.

Table 3. Average similarity of paragraphs across sections

	I	II	III	IV
I: Introduction	**0.32**	0.26	0.27	0.31
II: Methodology	0.26	**0.29**	0.27	0.26
III: Result	0.27	0.27	**0.31**	0.28
IV: Discussion	0.31	0.26	0.28	**0.30**

It is worthwhile to complement this analysis by adding the distance between paragraphs to the analysis. Figure 4 plots the average similarity between two paragraphs against the distance between them in the text. As each paragraph gets a sequence number in the processing phase it is easy to calculate the distance between them. The plot distinguishes between two groups, namely the distance between paragraphs inside one section opposed to the distance across sections. The solid line indicates the within section similarity and starts with the highest value. It rapidly declines with an increasing distance. The similarity between paragraphs across sections stars much lower and takes an increase and slow decline afterwards.

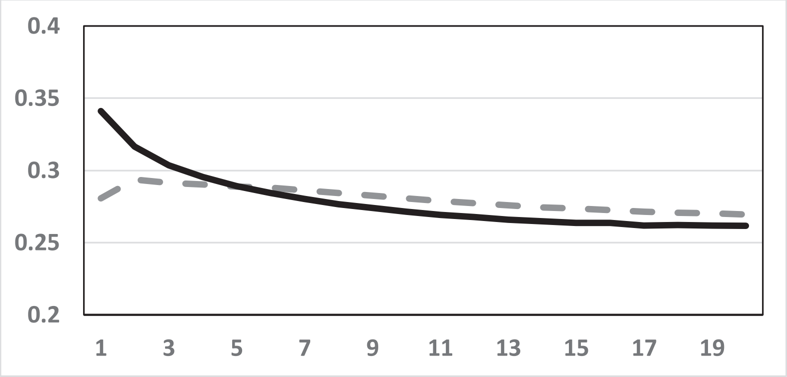

Figure 4. Average similarity between paragraphs related to the distance within the document. (Solid line: within one section, Dashed: across sections)

The overall image in figure 4 can easily be explained by the low similarity between the '*Methodology*' and '*Results*' sections with the two other sections. The main structure of PlosOne papers is either IMRaD or IRDaM with the '*Methodology*' or '*Result*' section in between '*Introduction*' and '*Discussion*' creating higher distance between these sections with higher similarity. Remarkable is the crossing of the two lines near a distance of 5 between paragraph. From then on, paragraphs from different sections are more similar than within sections. Probably, topics or themes already raised in a previous section are retaken in the light of the obtained results or applied methodology.

Between document similarity

The analyses in this next section will all focus on similarity across documents.

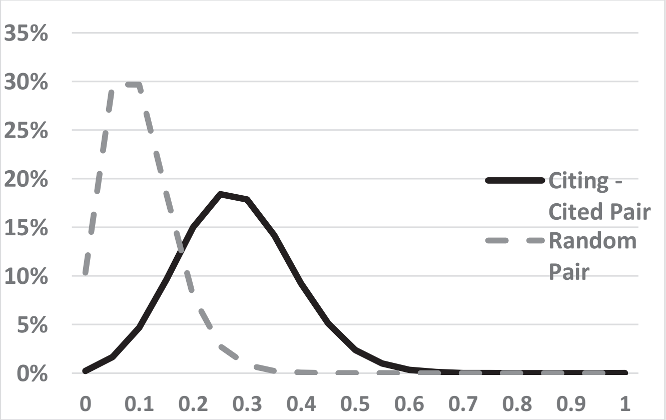

Figure 5. Distribution of similarity as measured through vector document embeddings of abstracts of document pairs (solid line: Citing-Cited document pair, dashed line: random pairs).

In order to have a baseline or reference point, the similarity between abstracts in citing-cited document pairs is gauged against the similarity between two randomly selected abstracts. The distribution of both sets of similarities have been plotted in figure 5.

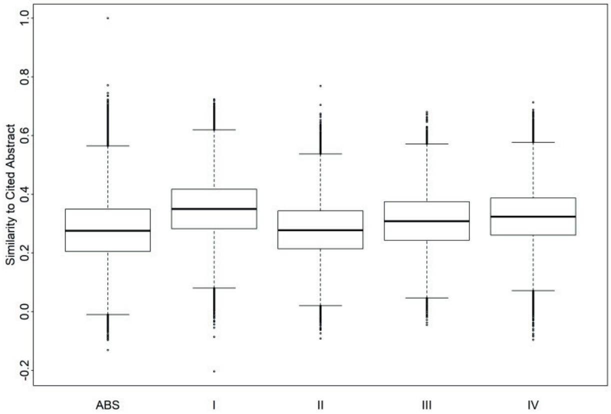

Figure 6. Distribution of similarity between abstract or citing section and abstract of cited document.

The similarity between random selected abstracts is just below 0.09, while the average for the citing-cited pair of documents is 0.28. The distribution of similarities of abstracts of citing and cited pairs of documents is also in figure 6. Here it is contrasted by the distribution of similarity of the paragraph in which the reference appears and the abstract of the cited document, grouped by citing section. Once more, paragraphs in the '*Introduction*' show the highest similarity with the cited abstract. The median in the second box is highest while the first box (abstract to abstract) has the lowest median. This shows clearly that the information in these individual paragraphs bear different content or information than the abstract.

For the last analysis, the similarity is calculated between the citing paragraph and all paragraphs in the cited document. A citation does not contain -it exceptionally does- a reference to the exact location of the relevant concept or topic in the cited document. This last analysis selects only those PlosOne papers cited at least 5 times by other PlosOne papers. Figure 7. plots the average similarity between citing paragraphs and cited paragraphs across different sections. A plot for each section at the citing side is given. Each plot contains a box per section in the cited document. Paragraphs from the '*Introduction*' and '*Discussion*' section are most similar with the '*Introduction*' in the cited document with 'Discussion' ranked second. This pattern changes when looking at the citing paragraphs in the '*Methodology*'-section. Here cited '*Methodology*' and '*Introduction*' score equally.

Discussion and Conclusion

The results obtained in this study support the statement that a more fine-grained approach using paragraphs is applicable in science mapping and that it will provide additional insights in the topic structure underlying scientific papers. As earlier observed (see Bertin et al. 2013), each section in a publication serves different purposes with distinct reference distribution. Here it is shown that there is also a textual difference between sections but also within sections. The further paragraphs are separated from each other in a section the less similar they are. The use of vector word and paragraph embeddings can be useful for several applications in quantitative science studies. In the following section, applications of intra- and inter document similarity are presented.

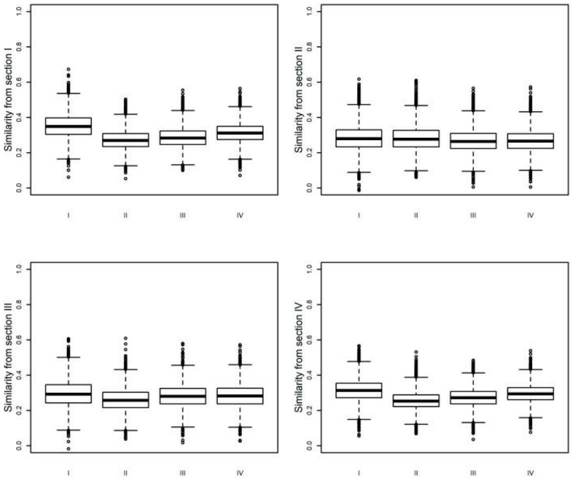

Figure 7. Distribution of similarity between citing section and different sections in cited document.

Applications and limitations

The use of intra-document similarity between paragraphs can extend the study of interdisciplinarity. Currently two main approaches are applied for the study of interdisciplinarity of scientific publications namely the use of subject classifications of cited references (Leydesdorff & Rafols, 2011) and the disciplinary profile of the researchers involved (Abramo et al., 2012). Using the lexical information embedded in the distinct paragraphs and sections combined with the similarity to cited documents can provide a novel third approach. Network-based statistics like node distance, centrality and modularity are appropriate measures for central concepts in the study of interdisciplinarity like disparity, balance and variety (Wang et al 2015).Another application of this fine-grained approach is in information retrieval. Context based word embeddings provide enhancements at both *needle* and *haystack* side. Key words in search strategies can be complemented by their specific context which defines their meaning and the same model is used to characterize the paragraphs at the haystack side. Moreover, other applications of word embeddings (see eg. Mikolov et al., 2013) have shown that mathematical operations on vectors like subtractions are possible and retain their topical characterization. This allows the creation of search strategies starting from a set of keywords without the need to list all possible alternatives or variations but also to provide a set of keywords or papers that are irrelevant to the search and should be excluded.

The novel approach presented in this study does not come without limitations. At first, there is the need for open access to the full paper in the required JATS-format. The procedure could be rewritten to be applicable on HMTL data or even on parsed PDF. However, the main advantage of JATS is that it specially targeted towards scientific journal articles and parsing is less prone to errors. The scoring of additional documents not in the original dataset is possible through the neural network algorithm. The obtained model can even be trained to incorporate these additional documents, but the procedure initially starts with the creation of a word vocabulary which cannot be updated. This puts a burden on the extensibility of the model as the proposed approach also takes the publication identifiers of the cited documents. These identifiers are merged into vocabulary as if they were words. The set of cited documents in the additional data set will thus be limited to the original set of cited documents. Other approaches for word embeddings like LSH or random projects suffer also from this limitation. The model reduces the document space from extreme sparse with hyper dimensionality into a dense matrix with limited predefined number of dimensions. Using such a dense matrix for the creation of document networks results in a near complete network where a similarity can be calculated for nearly any given pair of documents. It is very hard to use these near complete weighted networks as a basis for clustering techniques or community detection. Only the application of thresholds on the similarity can solve this issue which comes with computational constraints as the similarity of each pair of documents has to be calculated prior to the application of the threshold. Hashing algorithms like LSH can be used to solve this issue.The creation of the neural network model involves tuning several parameters like number of underlying nodes or dimensions, learning rate, learning iterations, minimum threshold for rare words, down-sampling rate for frequent words, sliding window length for the word context. With the last option, frequent words are removed with a probability relative to the inverse of their frequency which results in actual larger windows. The Word2Vec also provides two different learning approaches. Each of these parameters can have an influence on the final obtained model. More research is required to study the effect of this hyperparameter tuning on the final validity of the model and resulting vector embeddings.

Conclusion

Vector word and paragraph embeddings provide a novel approach for the calculation of within and between document similarities. The technique is used to create neural network based mathematical representations of text fragments of smaller size like paragraphs. Within such a vector space, the cosine of the angle between the vectors can be used to indicate the similarity between the underlying text fragments. The Word2Vec and Doc2Vec implementations provide an easy to use library for the creation of the word embeddings and similarity calculations. The application of the technique shows that the paragraphs in the '*Introduction*' and '*Discussion*' section are most similar to the abstract but that the '*Methodology*' has a much lower similarity with abstract. Combined with lower number of references in this section, the paragraphs are less presented in document-based approaches using abstracts and citations for the creation of document networks. When looking at citing-cited pairs of documents, the paragraph containing the actual reference to the cited paper shows a higher similarity with the abstract of the cited paper. This is especially the case with paragraphs from the introduction. The novel approach can have several applications in quantitative science studies like the study of interdisciplinarity or bibliometric aided information retrieval, but the technique suffers still from limitations which can damper the validity of the obtained results.

Abstract

The quantitative evaluation of research is currently carried out by means of indicators calculated on data extracted and integrated by analysts who elaborate them by creating illustrative tables and plots of results.

In this paper we propose a new approach which is able to move forward, from indicators' development to performance model's development. It combines the advantages of the Ontology-based data Access (OBDA) integration with the flexibility and robustness of a Visual Analytics (VA) environment. A detailed description of such an approach is presented in the paper.

Introduction: An advanced models' development approach

In recent decades, the rapid changes taking place in the production, communication and evaluation of research have been signs of an ongoing transformation. It has been stated that "we are living a sort of Middle-Age guided by the information and communication technologies (ICT) revolution, or the so-called *forth revolution* as described by Floridi (2014) which emphasizes the importance of information" (Daraio, 2019, p. 636). Largely, the current Middle-Age of research evaluation might be understood as the transition from a traditional evaluation model, based on bibliometric indicators of publications and citations to a modern evaluation, characterized by a multiplicity of distinct, complementary dimensions. This step is guided by the development and increasing availability of data and statistical and computerized techniques for their treatment, including among others the recent advancements in artificial intelligence and machine learning. Daraio and Glänzel (2016) show that that the complexity of research systems requires a continuous information exchange.

These changes produce different effects (see further details and references in Daraio, 2019, Table 24.2, p. 644) i) on the *demand side* (those that ask for research assessment) including an increase of institutional and internal assessments, ii) on the *supply side* (those that offer research assessment) including proliferation of rankings, development of Altmetrics, open access repositories, new assessment tools and desktop bibliometrics), iii) on *scholars* (the increase of "publish or perish" pressure, impact on the incentives, behaviour and misconduct, and increasing critics against traditional bibliometric indicators), iv) on the assessment process (increasing the complexity of the research assessment) and on the indicators' development.

Daraio (2017a) showed that the formulation of models of metrics (in this paper we will use metrics and indicators as synonyms) is necessary to assess the meaning, validity and robustness of metrics. It was observed that developing models is important for *learning* about the explicit consequences of assumptions, test the assumptions, highlight relevant relations; and for *improving*, document/verify the assumptions, systematize the problem and the evaluation/choice done, explicit the dependence of the choice to the scenario. Moreover, there are several *drawbacks* in modelling, which have to be taken into account. The main pitfalls relate to the targets that are not quantifiable; the complexity, uncertainty and changeability of the environment in which the system works, to the limits in the decision context, and, last but not least, to the intrinsic complexity of calculation of the objective of the analysis.

In this paper we depart from the traditional approach to indicators' development, based on the selection of a specific set of indicators, collection of the relevant data, cleaning of the gathered data, computation of the indicators and illustration of them in a plot or table. According to this traditional approach if you want to add a new data source or you want a different indicator you have to restart the process from the scratch.

We support an alternative approach based on an OBDA system for R&I data integration and access. An Ontology-Based Data Access (OBDA) system is an information management system constituted by three components: an ontology, a set of data sources, and the mapping between the two. An *ontology* in Description Logic (DL) is a *knowledge base*. It is a couple (pair) O=<TBox,ABox>, where TBox is the Terminological Box that represents the *intensional* level of the knowledge or the *conceptual* model of the portion of the reality of interest expressed in a formal way; and ABox is the Assertion Box that represents the *extensional* level of the knowledge or the *concrete* model of the portion of the reality expressed by means of assertions (instances). An ontology populated by instances and completed by rules of inference is defined as *knowledge base* (see e.g. Calvanese et al. 1998). The *data sources* are the repositories accessible by the organization where data concerning the domain are stored. In the general case, such repositories are numerous, heterogeneous, each one managed and maintained independently from the others. The *mappings* are precise specifications of the correspondence between the data contained in the data sources and the elements of the ontology. The main purpose of an OBDA system is to allow information users to query the data using the elements in the ontology as predicates.

The OBDA system, implemented with *Sapientia*, represents the ontology of multidimensional research assessment (Daraio, Lenzerini et al. 2015) and permits the extraction of relevant data coming from heterogeneous sources - maintained independently, and reasoning about the Performance Indicators (PI) of interest.

Daraio, Lenzerini et al. (2016a) showed the advantages of an OBDA system for R&I integration and Daraio, Lenzerini et al. (2016b) showed that an OBDA approach allows for an unambiguous specification of indicators according to its four main dimensions: ontological, logical, functional and qualitative. See also Lenzerini and Daraio (2019) where a detailed illustration of the usefulness of an OBDA approach for reasoning over the ontology about indicators of performance is reported. Even the simplest indicator of performance, such as number of publications has different conceptual aspects that the ontological commitment of the domain offers to the analyst (for additional details the reader is referred to Fig. 15.9 and 15.10 of Lenzerini and Daraio, 2019, pag. 368 and pag. 369).

The main contribution of this paper is making a step further, on our previous researches and to propose a new approach for the multidimensional assessment of research and its impact based on the combination of OBDA and Visual Analytics. This novel approach allows for the development and evaluation of performance models instead of the traditional indicators' building system.

Combining OBDA and Visual Analytics

The traditional way to define indicators relies on an *informal definition* of the indicator as the relationship between variables selected among a set of data collected and integrated "ad hoc", specific for the user needs (*silos based* data integration approach). This means that when a new indicator has to be calculated, the process of data integration has to restart since the beginning because the dataset created "ad hoc" for an indicator is not reusable for another one.

The contribution of an OBDM approach to overcome this traditional indicator development approach is twofold. First of all, it permits the *free* exploration of the *knowledge base* (or information platform) created to identify and specify new indicators, not planned or defined in advance by the users. This feature would be particularly useful to face two recent trends in user requirements, namely *granularity* and *cross-referencing* (see Daraio and Bonaccorsi, 2017 for a discussion on university-based indicators). Secondly, it allows us to specify a given indicator in a more precise way as described in Lenzerini and Daraio (2019).

In this paper we develop further this approach combining it with the main strengths of Visual Analytics. Visual Analytics (Cook & Thomas, 2005, Keim et al., 2008) is "the science of analytic reasoning facilitated by interactive visual interfaces"; through the connection of the analytical calculation with visualization and interaction by the human user, this interdisciplinary approach enhances the exploratory analysis of data, allowing to represent multidimensional data in a simple way through innovative visual metaphors. Further it allows navigation in the data space, in order to obtain an overview of the eventually tunable to the required level of detail, the ability to apply complex analysis workflows that aim at explainability, the ability to obtain summary reports of the findings discovered during the analysis phase. See Figure 1 for an overview.

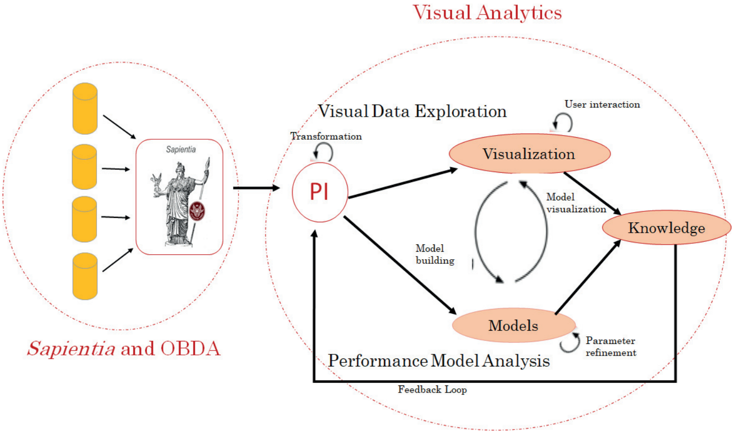

Figure 1. An illustration of our approach that combines *Sapientia*, OBDA and Visual Analytics. PI states for Performance Indicator.

The Visual Analytics approach developed in this paper allows us to move from Performance indicators development to Performance model development, by exploring and exploiting the modelling and the data features within the flexibility of a Visual Analytics environment.

This allows a multi-stakeholder viewpoint on the model of PI, the assessment of the sensitivity and robustness of the PI model in a multidimensional framework.

In the next section we outline the main features of *Sapientia* (the Ontology of Multidimensional Research Assessment). After that we present our Visual Analytics environment for the performance model's development together with an illustration of its potentialities. The final section concludes the paper.

OBDA at work through *Sapientia: The Ontology of multidimensional research assessment*

Sapientia, the Ontology of Multidimensional Research Assessment (Daraio et al. 2015, 2016a, 2016b), models all the activities relevant for the evaluation of research and for assessing its impact (see Figure 2 for an outline of its modules). For impact, in a broad sense, we mean any effect, change or benefit, to the economy, society, culture, public policy or services, health, the environment or quality of life, beyond academia.

The *Sapientia* ontology has been developed using the Graphol visual language (http://www.dis.uniroma1.it/~graphol/, Lembo et al. 2016), that can be easily translated into standard ontology languages like Owl.

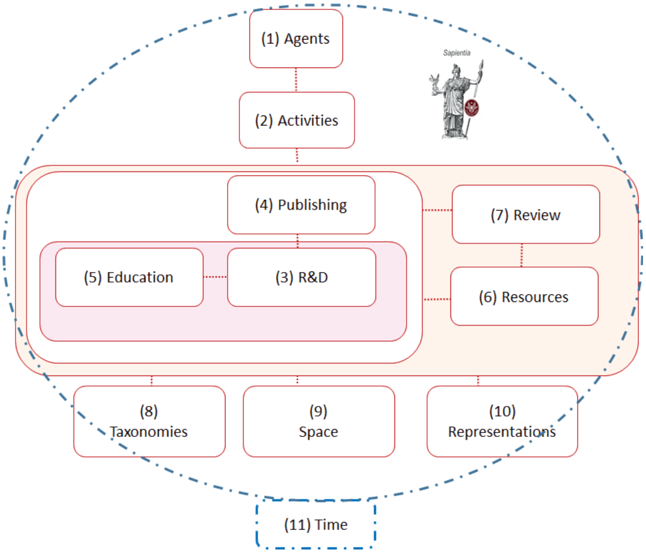

Figure 2. Modules of *Sapientia* 3.0. 1. Agents: describes all human actors and institutions involved in the education, research and innovation process. 2. Activities: describes the activities and projects the agents of the previous module are involved in. 3. R&D: describes the different products (e.g., publications, patents) that are produced in the knowledge production process. 4. Publishing: describes how knowledge products are published and made available to the public. 5. Education: introduces concept related to universities and courses. 6. Resources: describes all the ways and institution can be funded. 7. Review: describes the process entities related to the publishing activity. 8. Taxonomy: describes the elements that allows to define taxonomies applied to the different modules. 9 and 11: Space and Time: allow to describe respectively geographical entities and time instants and ranges. 10. Representation: allows to describe the fact that single instances of other modules can be represented in different ways by the different sources used in *Sapientia.*

Sapientia acquires information from multiple sources, whose content can be overlapping. The same entity modelled in the *Sapientia* ontology can be represented in more than one data source, and even one data source could present (due to internal inconsistencies or design choices) the same entity multiple times in different forms.

Hence, we have the need to identify duplicated items and integrate the information obtained for each entity from any of the available sources.

In particular, at the ontology level we have created the concept of Representation. Entities modelled in the ontology of which we have different views from different data sources may have their own representation, which specializes the general Representation concept. This makes it possible to keep track in the ontology, through the mappings, not only of the modelled entities, but also of the way in which the information relative to the entities has been gathered from the data sources.

Data acquisition from the external sources makes use of the web service standards (REST, SOAP) when available.

For less frequently updated sources and sources that do not implement an API, data acquisition leverages in some cases the open source edition of Pentaho Data Integration (http://community.pentaho.com/projects/data-integration/).

Imported data are saved in a relational database (MySql). Each source is modeled independently so that its peculiar structure can be fully exploited.

Sapientia extract information, among others, from the following datasets:

- *Scopus*. A very large abstract and citation database of peer-reviewed literature, containing information about scientific journals, books and conference proceedings. Scopus provides information about authors' affiliations as well. The available REST interface allows to retrieve: document information, document citations data, percentiles data end journal percentiles data.
- *ETER*. The ETER (European Tertiary Education Register) consortium acquired extensive information pertinent to tertiary educational institution of many European countries. Data have been acquired by the consortium for the years 2011-2016 and are publicly available (https://eter-project.com).
- *DBLP*. A service that provides open bibliographic information on major computer science journals and proceedings. Data is available through massive XML files.
- The *InCites* (https://incites.thomsonreuters.com) dataset contains research indicators organized on a geographical base. Data can be downloaded in the form of CSV files that are then imported using an ad-hoc procedure.
- *Geonames* (http://www.geonames.org/) is a dataset that contains information about geographical areas at any level. The dataset can be freely download, and has been employed to match geographical entities from the different data sources.
- *Web of Science* database is going to be included as well.

The data manipulation layer of the *Sapientia*, which allows to populate the ontology from the data sources, is composed of an indexing module, an entity-resolution module and a normalization module.

In general terms, the *indexing module* creates and maintains up to date the indices that are used by the *entity resolution module* to implement the blocking functionalities that allow to keep the time complexity of the entity-resolution algorithms under control. This module has the dual purpose of easing the definition of the mappings toward the *Sapientia* Ontology, and creating the basis for a common interface of the entity-resolution algorithms. Indices inside the *Sapientia* application are implemented using the Hibernate search (http://hibernate.org/search/) library and the Lucene indexer and searcher (http://lucene.apache.org/).

Entity resolution is the task of connecting matching entities between different data sources. As this kind of process is exponential in complexity with the number of data sources and entities per data sources, it is split in two phases:

- *Blocking*, which allows very quickly, by employing indices to create groups of potential matching entities
- *Entity matching*, which finds matching entities inside clusters identified by blocking.

After matching entities have been recognized by entity resolution, the *normalization step* is employed in order to provide a uniform representation for the information contained in different and heterogeneous data sources. These uniform representations are called mappable entities. These mappable entities are mapped to ontology entities through an operation called mapping. *Sapientia* uses the Mastro Ontology-Based Data Access (OBDA) management system (http://www.dis.uniroma1.it/~mastro/?q=node/1). The Sapientia ontology, however, is defined over a richer language than the one supported by Mastro. Hence, we used the OWL2DL tool in order to obtain a simplified version of the Sapientia ontology that conforms to the DL-light language supported by Mastro.

The definition of the mappings in Mastro is XML based. There are three types of ontology predicate mappings: concept, role and attribute.

As suggested by the names, the concept predicate mapping refers to entities, the role predicate mapping puts entities in relation, populating a role, while the attribute mapping relates an entity with a constant, which is the value of its attribute.

Some examples of extraction and mapping of relevant data

In order to show the potential of the proposed approach, we will show how indicators can be extracted from the ontology and grouped according to a specific level of analysis. In the illustration identified as European denoted Nomenclature of Territorial Units for Statistics (NUTS) code. The modules of the ontology interested in this query are:

- The *Agents module*, which contains the concept of University as a specialization of the concept of Organization. An Organization has an Organization State, which represents the evolution of the Organization in time, and that refers to the Residence.
- The *Space module* that contains the concept of Residence as a specialization of a Position. A Position has an Entrance, which is localized in an Address inside a City. The City is a Territory, and European Cities are European Territories that can be aggregated by NUTS codes.
- The *Taxonomy module* where an Organization is contained in a Taxonomic Unit. Each Taxonomic Unit has a State that has indicators as attributes.

For a specific university denoted by its Eter ID, we can for example compute the cardinality of academic staff with the following SPARQL query :

```
select ?academic_staff {
     ?org sapientia:has_place_in ?taxon_unit .
     ?org a sapientia:University .
     ?taxon_unit sapientia:has_state_of_taxonomic_unit ?state_tax .
     ?state_tax a sapientia:Present_state .
     ?state_tax sapientia:teacher_population ?academic_staff .
}
```

In order to group by a specific NUTS codes, it is possible to extend the previous query as follows:

```
select SUM(?academic_staff), ?nuts2 {
     ?org sapientia:has_place_in ?taxon_unit .
     ?org a sapientia:University .
     ?taxon_unit sapientia:has_state_of_taxonomic_unit ?state_tax .
     ?state_tax sapientia:teacher_population ?academic_staff .
     ?state_tax a sapientia:Present_state .
     ?org sapientia:has_state_of_organization ?org_state .
     ?org_state a sapientia:Present_state .
     ?org_state sapientia:has_residence ?resid .
     ?resid a sapientia:Legal_residence .
     ?resid sapientia:has_entrance ?entr .
     ?entr a sapientia:Address .
     ?entr sapientia:is_in_the_city ?city .
     ?city a sapientia:European_territory .
     ?city sapientia:is_territory_part_of ?region .
     ?region a sapientia:Small_europen_region .
     ?region sapientia: NUTS2ref ?nuts2 .
     ?region sapientia: NUTS2ref ?nuts1 .
     ?region sapientia: NUTS2ref ?nuts3
}
GROUP BY ?nuts2
```

Where the results have been grouped by NUTS2. It is possible to easily modify the query in order to group by other levels of NUTS. In a similar way, *mutatis mutandis*, it is possible to extract the data and indicators that will be used for the Performance Indicator and model development that is described in the next sections.

The Visual Analytics environment

This section describes the Visual Analytics environment and its main features. The developed solution uses Visual Analytics techniques to represent data from publications and education obtained from the OBDA approach described in the previous section, and complete the workflow. The system is implemented through Web technology. Clearly the large quantity of indicators and basic sizes for the different units of analysis, including the territorial ones, and in the different years of analysis increases exponentially the cardinality of data to be analyzed; in this respect, the display part allows to obtain a visual overview of the data in a very simple form, and the interaction capabilities allow the user to navigate in this overview and conduct detailed analysis up to the desired level. The user is also supported in the discovery of any elements of analysis of interest through a process of *data exploration* that does not require a prior analysis goal.

In addition to the data exploration capacity there is a second area explicitly aimed at analyzing the model development and performance computed on these indicators, based on the definition and exploration of performance models. The environment is instantiated on European research and education institutions as a case study. The user can, on one hand, analyze the performance of the various institutions with respect to a performance model, in order to analyze the positioning of the institutions of interest; additionally, it allows to explore different performance models and to evaluate their goodness and fitness. Further, it is also possible to evaluate the goodness of the proposed models, analyzing their variability and conducting sensitivity analysis in order to evaluate which parameters of the model (whether inputs or resources, contextual factors or outputs) contribute more to the performance of the institution with respect to the chosen model. The following subsections will provide a description of the features of Visual Analytics environment.

Data Exploration Environment

The first panel that composes the Visual Analytics environment is the data explorer environment. This environment consists of three main views depicted in Figure 3.

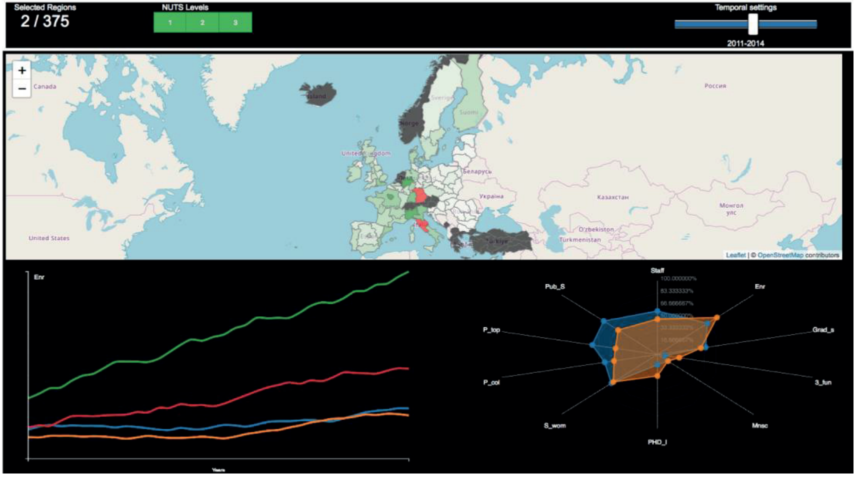

Figure 3. Data Exploration Environment

These three views are:

-*Geographic view*: which allows for geolocating of the different institutions with respect to territorial units on a geographic layer (using Leaflet.js framework, based on OpenStreetmap) is used. The map is navigable on 5 different levels of detail, where the first four follow the NUTS categorization from 0 (Nations) to 3 (Provinces) and the last one relates to single institutions. The user can at any time change the level of aggregation through a tab that shows the different available levels.

The color of each element of the map reflects an indicator (basic or derived) of, on a green scale that identifies the values (white: low value, dark green: high value). The gray color codifies the absence of data for the particular territorial unit. A slider allows the analyst to scroll through the various years and conduct a temporal analysis on the available data, looking for institutions showing a high variability through a "time-lapse".

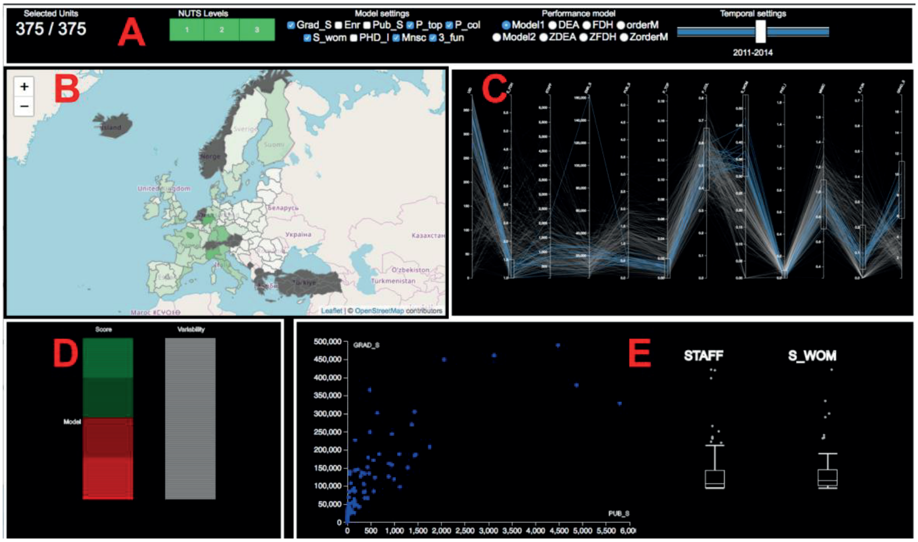
-*Radar view*: this view follows the visual paradigm of the radar diagrams (Von Mayr, 1877) , which represent the dimensions of a dataset one per axis, with the axes arranged in radial form starting from the center. The indicators are arranged one per axis and the graph presents several lines that join the points on each axis in the number of one per institution or territorial unit. When the user selects one or more territorial units, the corresponding splines are highlighted, in order to allow an easy visual comparison between the different territorial units selected on their different dimensions. It is also possible to highlight a dynamic average trend, consisting of a line that connects the different averages on the respective axes, in order to compare the performance of a territorial unit, or generally of a given unit of analysis, not only to other units but also to the aggregate behavior between the territorial units.

-*Linechart view*: This visualization allows analyzing the time course of the evaluation measures used for the units. It is possible to analyze both multiple territorial units to compare the trend of the same measure on them, and to analyze multiple measures on the same territorial unit, in order to have an overview of the progress of the unit itself, and a combination based on multiple territorial units and multiple measures. In this case the color-coding outlines all the measures belonging to each single territorial unit.

The combined use of these views, possibly guided by the definition of specific PIs, allows more powerful dynamic exploration of the model data of the territorial units compared to the classical approaches, making the user able to obtain an overview of the general trend and specific details on the individual units, subsequently allowing to refine the analysis through the visual selection of appropriate subsets of information. The approach therefore allows the exploration of s*pecific scenarios* chosen by the user in *real-time*, without precomputation, which better support the formation and validation of hypotheses and the identification of areas of interest on which to conduct further analysis or to be used for reporting activity.

Performance Model Analysis Environment

This environment is dedicated to the analysis of performances of the model used for analyzing the units. The visual environment is therefore more complex than the Data Exploration one, as shown in Figure 4.



Selected Units 375 / 375

NUTS Levels 1 2 3

Model settings ☑ Grad_S ☐ Enr ☐ Pub_S ☑ P_top ☑ P_col ☑ S_wom ☐ PHD_I ☑ Mnsc ☑ 3_fun

Performance model ● Model1 ○ DEA ○ FDH ○ orderM ○ Model2 ○ ZDEA ○ ZFDH ○ ZorderM

Temporal settings 2011-2014

Figure 4. Performance Model Analysis Environment

The environment consists of a command bar (A), a geographical view borrowed from the Data Exploration environment (B), a view based on parallel coordinates (C), a view of the rankings due to the selected performance model (D) and finally a view based on scatter-plot and box-plot that allows to conduct sensitivity analysis on the parameters of the selected model (E). The features of the individual views are described below.

-*Command bar*: this area identifies the main analysis commands that will affect the selections in all remaining views. From left to right we have:

-the counter of the territorial units active with respect to the total (the territorial units contained in the current selection)

-a tab that allows to select the aggregation level on which to conduct the analysis

- the parameters and measures of the performance model, which can be activated using the appropriate checkboxes. This command allows to re-parameterize a model (among those available) in order to conduct a different type of analysis of performance.

-The model selector, which allows you to choose between 8 families of performance models, ranging from custom model defined by the Analyst (Model 1 and Model 2) to efficiency models, Data Envelopment Analysis (DEA), Free Disposal Hull (FDH), orderM, and their conditioned variants ZDEA, ZFDH, ZorderM. An overview on these performance models can be found in Daraio (2019).

-The time selector, which allows to evaluate the result of the chosen model with respect to a temporal interval that can be controlled by means of a slider.

-*Geographical view:* this visualization follows the same operating principle illustrated for the Data Analysis Environment. In this instance, however, the color linked to each individual territorial unit is proportional to the unit's performance score with respect to selected model. In this way the user can immediately get an overview of the different performance levels given the chosen hierarchical level, model and time interval. The user can zoom in on the map in order to get more details on individual portions of the map. It is also possible to use the map as a highlighting mechanism: by clicking on one or more units, these are highlighted in red on the map and in all other coordinated views, allowing to identify a subset of data of interests starting from geographical coordinates of the unit.

-*Parallel coordinates*: this view shows all the dimensions that are part of the model (inputs, possible conditioning factors, outputs) plus the year of analysis and the ID of the units. The purpose of this visualization is to explore the relationships that exist between these quantities, in order to decide whether or not to keep them in the selected model. From the visual point of view, each of the dimensions is represented as a vertical axis, and each unit as a line that joins the values it has on each axis. Through brushing operations on individual axes, it is possible to perform multi-filter operations on several dimensions, making possible to select very complex filtering expressions while maintaining the ease of creating these filters: by dynamically define new intervals on the various dimensions, and immediately verify the cardinality and the characteristics of the resulting subset, the analyst can explore several combinations and discover relations among dimensions (see Figure 5).

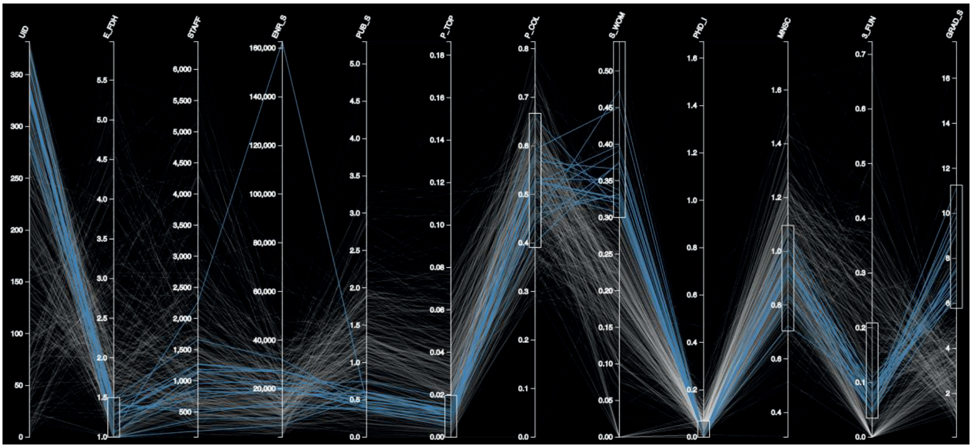


Figure 5. Example of parallel coordinates filter. Axes, from the left: UID is the institution id number, E_FDH is the FDH (in)efficiency score (equal to 1 means efficient; the higher it is, more outputs the unit could proportionally produce to become efficient) STAFF is number of academic staff in FTE (Full Time Equivalent), ENR_S is number of total enrolled students per academic staff, PUB_S is number of publications in WoS (fractional count) per academic staff, P_TOP is number of publications in top 10% of highly cited journals per academic staff, P_COL is percentage of papers done with international collaborations, S_WOM is share of women professors on total academic staff, PHD_I is PhD intensity, MNCS is Mean Normalized Citation Score (1 corresponds to the world average, >1 above (<1 below) world average), 3_FUN is share of third party funds in %, GRAD_S is total number of graduates per academic staff. The filter shows that among the most efficient units in teaching and research (i.e. E_FDH = [1 1.5]) there are those teaching oriented institutions (with the highest values of GRAD_S) in which the S_WOM is the highest ([0.30-0.50]): these are universities with almost zero PhD intensity that are able nevertheless to produce a small fraction of P_TOP publications with MNCS around the world average.

In addition, by drag and drop interaction, it is possible to exchange all the axes with each other, in order to better highlight any correlations, anti-correlations or similarity characteristics on specific subsets of data among dimensions. Any findings, as mentioned above, serve to better understands the results coming from the performance model used.

-*Rank analysis*: This view supports the tasks of exploring the performance scores of the individual units, and the sensitivity analysis on the model, in terms of estimating the contribution of each individual parameter of the model to the performance scores. The visualization is composed of two bars representing rankings, where the units are ordered according to the performance score from top (high performance score) to bottom (low performance score). Each unit is represented as a rectangle, whose color derives from the calculation of the distribution of the performance scores and from the assignment of a color to each of the 4 quartiles (the 3rd and 4th quartiles with deeper shades of green, the 1st and 2nd with deeper shades of red). An informative tooltip, activated by mouse-hover on each rectangle, allows to obtain accurate information on the performance of the unit. The second bar is initially completely gray, and is activated when individual elements (inputs, conditioning factors) of the model are selected / deselected from the command bar: in this way it is possible to evaluate the displacement in the rank of each single unit with respect to addition/deletion of a parameter of the model, and therefore be able to evaluate the stability of the model compared to the performance scores produced, and the sensitivity of the performance model in terms of contribution that any parameter produces in the ranking (see Figure 6).

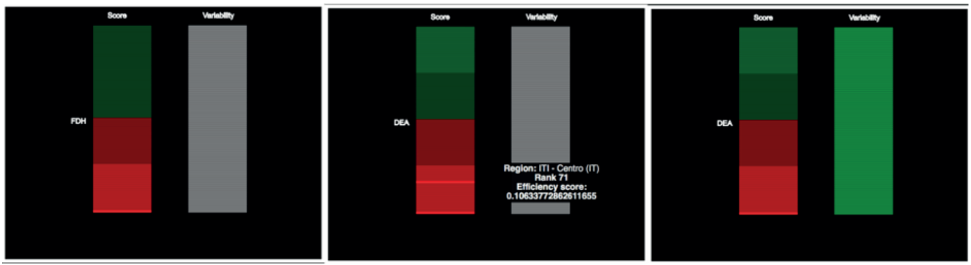

Figure 6. rank analysis obtained using a complete FDH model (left); the same chart is instantiated through a DEA model, and the tooltip reports the score for the "Italia Centro" territorial unit (center); finally, the result on the variability obtained by removing the output factor PUB_S and including P_TOP (right). As you can see, the whole bar is green, which means that the units rank remains stable with respect to this input, which could be replaced by another more significant input.

Sensitivity analysis: This view expands the sensitivity analysis capabilities, already introduced in the Rank Analysis view. The visualization uses two different visual paradigms to relate the different parameters that constitute the performance model: in the first one, a scatter plot, the relation between the conditioning factors (if present) and the outputs is reported. Input factors are instead reported as a distribution in the form of a box-plot for each input factor. The interactivity of this chart allows to select disjoint sets of values from each box-plot and inspect the propagated filter on the entire visual environment. It will be possible to analyze the relationship between the various elements of the performance model in a more precise and granular form, identifying from the distribution subsets of interest which will eventually correspond to the selection of a subset of units that respect the imposed constraints. The effect will therefore support the sensitivity analysis of the model but also support the explorative analysis of the data through filter operations based on factors of the model (see Figure 7).

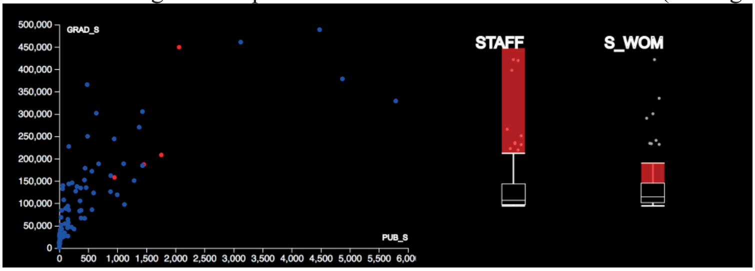

Figure 7. Example of data filtering: with respect to all the units, the selection is composed by high outliers for academic staff (STAFF) and the 4th quartile for percentage of women staff (S_WOM); the resulting points are highlighted in red in the scatter plot, and the unit can be identified by mouse-hover.

Conclusions

In this paper we leveraged on the research based on *Sapientia* and OBDA combining it with a Visual Analytics approach. The new approach proposed allows us to move from Performance indicators development to Performance model's development, by exploring and exploiting the modelling and the data features within the flexibility of a Visual Analytics environment. This allows a multi-stakeholder viewpoint on the model of PI, the assessment of the sensitivity and robustness of the PI model in a multidimensional framework as illustrated in the previous section.

Abstract

In this paper we studied bibliographic reference mistakes. Bibliographic references are an important part of scholarly publishing and are also crucial for visibility and accessibility of studies in the databases. We have searched how much of the bibliography of the works published in the Turkish Librarianship journal appeared in the Web of Science (WoS) citation database. Between 2015 and 2017, a total of 2959 studies, 2707 (91.4%) of which placed in the WoS, appear in the reference lists of 192 studies in Turkish Librarianship. 96 (38%) out of the 252 remaining non-indexed sources in WoS have been created in accordance with the original APA rules. Therefore, the reason why these sources are not indexed is either due to minor errors made by the authors or to the indexing algorithm of WoS.

Introduction

Bibliographic references are an integral part of scientific publishing in the process of creation and dissemination of information. This is also one of the areas where authors make the most mistakes. This may be due to the inattention of the authors or their lack of knowledge. Besides that, numerous bibliographic reference standards which are used for different scientific areas (Park, Mardis & Ury, 2011) also add to the mistakes. In recent years, the diversity of the resources used in research, with the widespread use of internet and electronic resources, has also made way for more mistakes in reference. Especially in classical, traditional areas (such as history, literature, archeology) these updates are not well known by the authors. Moreover, the fact that different journals in one area request different bibliographic standards is confusing the authors.

In bibliographical mistakes, it is known that there are mistakes caused by the inattention of the author as well as unethical citations (citation from secondary resources) (Bahar et al., 2012; Lok, Chan & Martinson, 2001; Oermann, Cummings & Wilmes, 2001). These mistakes may also arise from the inattention of journal editors (Oermann, Cummings & Wilmes, 2001). It does not offer an example of comprehensive bibliography preparation to many journalists. Again, the use of non-updated standards also increases the mistakes (Onwuegbuzie, Hwang, Combs, and Slate, 2012). Localized standard rules also can increase these mistakes by creating confusion.

The most important problem caused by such mistakes in given situations is the issue of appearance in citation databases of many resources with erroneous reference. When a study that has bibliographical mistakes is indexed in the citation databases, citations that do not comply with the standard or given incorrectly are not in place in the mentioned databases. For example, in a study, 19 references are shown in the database in which the study is indexed; although 20 references were used. This suggests that the missing reference is given incorrectly. It is necessary that the location and description information of the resource is given in full, so that the cited resource can be easily accessed (Moorthy, 1988).

In this study, we have searched how much of the bibliography of the works published in the Journal of Turkish Librarianship appeared in the Web of Science (WoS) citation database. We discussed the reasons why the resources not included in WoS are not indexed.

Method

The Turkish Librarianship was indexed in the ESCI (Emerging Sources Citation Index) of WoS in 2015. For this reason, we have analyzed articles indexed since 2015. In total, 192 articles covering 2015-2017 period were downloaded from WoS. With the data available, we checked from the web page of the journal and compared the relevant bibliography of articles. We were able to evaluate the bibliography of the articles written in Turkish and English, as the language of the article is included in the metadata in WoS (see Figure 1).

Figure 1. The sample of data set

Findings

Between 2015 and 2017, 192 studies which were published in 12 issues of the Journal of Turkish Librarianship have been indexed in WoS. Eight of these studies are in English. Between 2015 and 2017, a total of 2959 studies, 2707 (91.4%) of which placed in the WoS, appear in the reference lists of 192 studies in Turkish Librarianship. 20% or more of the studies in the reference lists of 16% of 192 studies (N=30) have not been indexed. Keeping in mind that 88 of them (46%) do not have any references, more than 20% of the resources in the reference lists of 32% (N=30) of the resources that have reference have not been indexed.

As some studies have not been indexed at all, sometimes extra studies have been indexed. WoS also includes the bibliographic record of the book introduced in the book introductions into the reference list. 25 of the 192 studies in our dataset are in this way.

The indexing rate of the reference list of English sources is 98.6%. 227 of the 230 resources in the reference list of the English source have been indexed. The type of three non-indexed studies are in the website format. In Turkish sources this rate is 91.4%. In our opinion, this difference is closely related to the localization of the APA rules. Due to the syntax differences in languages, the standard structure has been corrupted and the local rules have moved away from being a machine-readable standard.

Figure 1 shows the distribution by type of 252 sources from the studies in the reference list of 192 studies, which are not indexed in WoS for a variety of reasons.

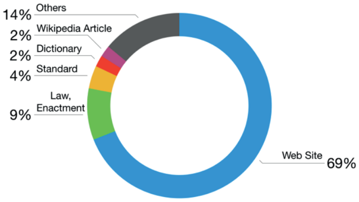

Figure 2. Distribution by type of 252 sources which are not indexed in WoS

Conclusion

- 96 (38%) out of 252 non-indexed sources in WoS have been created in accordance with the original APA rules. Therefore, the reason why these sources are not indexed is either due to minor errors made by the authors or to the indexing algorithm of WoS.

- The remaining 156 resources (62%) have not been indexed although prepared in accordance with "localized APA rules (Turkish version)".

- Disruptions related to the localized rules mostly arise from the syntax differences in the Turkish and English language rules. For example, according to APA rules, the phrase "Retrieved from" is used before the address is given. On a localized copy, "adresinden erişildi (accessed from address)" or "erişim adresi: (access address:)" phrases are used after the access address is given. Both the presence of the ":" sign and the corresponding pattern given before the access address lead to indexing problems.

- Apart from this, there are also resources not indexed by WoS even if they conform to APA style. Legal entity or organizations are indexed as title instead of author; or as [Anonymous] if the author name does not have a comma. At the entrance of the website, if there is a comma in the section up to the date, the author name is indexed as the journal name.

Abstract

Maps of scientific knowledge are generally based on citation analysis and therefore reveal how disciplines draw from each other to produce new knowledge. Although subject headings as well as their co-assignments represent the topics and their relationships within the journal article or book, they rarely have been used for mapping science. This study attempts to map the life science based on the Medical Subject Headings (MeSH) as well as their co-assignment at the paper level, which could advance the knowledge in mapping science.

Introduction

The purpose of mapping science is to visualize the scientific structure and the evolution of scientific inquiry (Börner, Theriault, & Boyack, 2015; Klavans & Boyack, 2015) by classifying science and relating the classes, which are generally derived from the analyses of scientific literature elements such as authors, journals, disciplines or other information (Klavans & Boyack, 2009). Although citation analysis is the dominant method for generating maps of science, expert judgements, subject categories, topic modelling, course descriptions, and subject headings could also be used to map the science.

Medical Subject Headings (MeSH) are controlled vocabularies for indexing journal articles and books in the life sciences, which represent all topics discussed within the journal article or book. Since a journal article or book could be assigned multiple MeSHs, the MeSH co-assignments could be used to measure the relationship between two medical topics by which the structure and evolution of life science could be mapped. The purpose of this study is to generate a map of life science using the MeSHs.

Related Works

Expert judgment was first used for mapping science. Bernal (1939) drew the first map of science representing the hierarchical structure of scientific topics by hand. Small and Griffith (1974) created the first citation-based map of science using co-citation analysis. Since then, citation analysis including direct citation (Boyack & Klavans, 2014b; Pan, Zhang, & Wang, 2013; Waltman & Eck, 2012), bibliography coupling (Boyack, 2008), co-citation (Boyack & Klavans, 2014a; Braam, 1991a, 1991b; Small, 1999) was widely used for mapping science.

Other methods in addition to the citation analysis were also used for mapping science. A map of science could be generated based on the co-occurrence of words in titles, abstracts or keywords using the co-word analysis (Ding, Chowdhury, & Foo, 2001; Leydesdroff, 1989; Peters & van Raan, 1993a, 1993b; Rip & Courtial, 1984). Balaban and Klein (2006) mapped science using undergraduate course pre-requisites at Texas A&M University. Suominen and Toivanen (2016) generated a map of science using topic modelling based on the latent patterns in texts retrieved from the Web of Science (WoS).

Subject headings was also applied to generating the map of science. Shu, Dinneen, Asadi, and Julien (2017) produced a map of science based on non-fiction books and their Library of Congress Subject Heading (LCSH) co-assignments. Leydesdorff, Comins, Sorensen, Bornmann, and Hellsten (2016) tried to compare the MeSH with cited sources using clustering and mapping. However, a map of life science based on MeSH has not been generated, which will be addressed by this study.

Method

In this study, in addition to MeSH co-assignment as discussed above, MeSH of citing/cited papers was also used to generate the map as the contrast. Although each MeSH term represents a topic discussed in the journal articles or papers, MeSH terms representing the major topics are marked in the PubMed. Each pair of the major MeSH terms between citing and cited papers also represents the relationship between two major medical topics. Leydesdorff et al. (2016) point out that the citation (citing/cited) map indicates a core structure of life science while the MeSH map shows the relevance of the life science research. Thus, two maps generated from two different approaches were compared in this study.

Data

In this study, 3,344 research papers published in four top medical journals (i.e., *The Journal of the American Medical Association, The Lancet, New England Journal of Medicine*, and *The British Medical Journal*) between 2015 and 2017 as well as their cited references were retrieved from Web of Science (WoS). A version of MEDLINE database integrated into the WoS was used as the linkage between WoS and PubMed in which a PubMed ID and MeSH terms were assigned to each journal article. As noted, not all papers are covered by both WoS and PubMed; in this study, only papers, either citing or cited, with a PubMed ID were included. Eventually, as Table 1 shows, 2,577 papers as well as their 80,782 cited references were collected under investigation; 5,119 and 16,582 MeSH terms were assigned to these citing papers and cited references respectively.

Table 1. Distribution of Papers and Cite References under Investigation in the Study

Journal	*Number of papers in WoS*	*Number of papers under investigation (citing paper)*	*Number of Cited Reference*	*Number of MeSH Terms (citing paper)*	*Number of MeSH Terms (cited reference)*
The Journal of the American Medical Association	658	516	13,889	1,749	9,589
The Lancet	963	658	25,459	2,062	8,696
New England Journal of Medicine	1,003	841	19,866	2,424	11,858
The British Medical Journal	720	562	19,704	2,926	11,812
Total	**3,344**	**2,577**	**80,782**	**5,119**	**16,582**

Note: Since one reference or MeSH term could be cited or assigned to different papers, the sum of the number of cited reference and the sum of number of MeSH term of four journals are higher than the totals in the last row.

Data Treatment

MeSH terms are organized as a 14-level tree structure, representing medical topics from broad to specific. This tree structure starts with 16 level-1 MeSH terms and 118 level-2 MeSH terms, on which the maps of life science were based. Assigned MeSH terms at level 3 or lower were re-assigned to their parent level-2 or grandparent level-1 MeSH terms. This method of reassignment to broader or more general abstraction levels, has been used in library classification mapping where its robustness has been confirmed (Shu et al., 2017).

As shown in Table 2, four datasets were finalized to produce four maps of life science: MeSH co-assignment map at level 1, MeSH co-assignment map at level 2, MeSH citation map at level 1, MeSH citation map at level 2. For each dataset, MeSH terms as well as their co-assignments or citation pairs (major MeSH terms between citing and cited papers) were imported into graph-drawing software *Gephi* to generate the visual map of life science. Each MeSH term was a node while each MeSH co-assignment or citation pair was an edge in the map. The number of assignment of each MeSH term determined the size of node while the number of co-assignment or citation pair decided the weight of each edge. Although the number of citation pairs are much higher than the number of co-assignments in these datasets, they could be normalized when producing the map through Gephi settings.

Table 2. Four Datasets for Four Maps of Life Science

Map	*Number of MeSH term*	*Number of unique MeSH co-assignment or citation pair*	*Total number of MeSH co-assignment or citation pair*
Co-assignment at level 1	16	105	104,832
Co-assignment at level 2	107	3,305	96,776
Citing/cited at level 1	16	110	818,944
Citing/cited at level 2	113	4,767	1,015,203

Results

Figure 1 shows the two maps of life science at the MeSH term level 1 containing 16 nodes/105 edges (lower) and 16 nodes/110 edges (upper) respectively. Nodes are level 1 MeSH terms while edges represent their relationship (i.e., co-assignment and citation pair respectively). Edge width is proportional to the number of co-assignment or citation pair between the two MeSH terms, and the node and label sizes are proportional to the number of assignments or citations.

Figure 1. MeSH citing/cited map (upper) and co-assignment map (lower) at level 1.

The difference between the co-assignment map and the citation map is not significant. A strong triangle relationship among *Diseases*, *Chemicals and Drugs*, and *Analytical, Diagnostic and Therapeutic Techniques, and Equipment* was found in both maps. Indeed, as Table 3 indicates, the top 10 MeSH terms in the both maps are in the same order and similar shares.

Table 3. Top 10 MeSH terms (Level 1) in Co-assignment Map and Citing/cited Map

MeSH	*Co-assignment Map*	*Citation Map*
Diseases	23.36%	22.12%
Anatomy	16.82%	17.7%
Phenomena and Processes	14.95%	15.04%
Chemicals and Drugs	14.02%	14.16%
Analytical, Diagnostic and Therapeutic Techniques, and Equipment	6.54%	6.19%
Health Care	5.61%	5.31%
Organisms	3.74%	4.42%
Psychiatry and Psychology	3.74%	3.54%
Anthropology, Education, Sociology, and Social Phenomena	2.8%	2.65%
Technology, Industry, and Agriculture	2.8%	2.65%

The color-coded legend of level 1 MeSH terms (see right of Figure 2) were used in the level 2 maps as shown in Figure 2. Nodes are level 2 MeSH terms as the colours of nodes represent their parent MeSH terms at level 1. Some differences were found when comparing the co-assignment map (lower of Figure 2) and the citation map (upper of Figure 2). The distribution of MeSH of citing/cited papers is skewed as some large nodes and wide edges appear in the citation map, while the distribution of MeSH co-assignments is more balanced. However, comparing with Figure 1, Figure 2 is visually complex due to high connectivity between the nodes and overlapping edges.

Figure 2. MeSH citing/cited map (upper) and co-assignment map (lower) at level 2.

Discussion and Conclusion

In this study, four maps of life science were generated using the MeSH terms assigned to 2,577 papers published in four top medical journals between 2015 and 2017 as well as their cited reference. Few difference was found when comparing the co-assignment map with the citation map at the MeSH level 1. It indicates that the MeSH co-assignment representing the relationship among different medical topics could also be used to map the life science comparing to traditional citation-based maps generated by the citing/cited relations. The results of this study could form a foundation for future studies mapping the life science using MeSH terms.

In addition, this study found the difference in terms of the MeSH term distribution between the co-assignment map and the citation map at the MeSH level 2, which could partly be due to the different functions between subject headings and citations. Subject headings emphasize the correlation of all related topics discussed in the journal articles or books while citations measure the similarity of citing and cited documents, which has been addressed by Leydesdorff et al. (2016).

As a research-in-process paper, this study only sampled 2,577 research papers from four top medical journals, a full dataset containing all medical articles should be investigated in the future studies. In addition, different visualization methodologies, in turn stemming from choice of visualization software, may also influence the visualization of the map, which should also be addressed in the future studies.

Abstract

In our paper we seek to address a shortcoming in the scientometric literature, namely that, given the proliferation of algorithmic approaches to topic detection from bibliometric data, there is a relative lack of studies that validate and create a deeper understanding of the topical structures these algorithmic approaches generate. To take a closer look at this issue, we investigate the results of the new Leiden algorithm when applied to the direct citation network of a field-level data set. We compare this 'internal' perspective which is constructed from the citation links within a data set of 30,000 publications in invasion biology, with an 'external' perspective onto the topic structures in this research specialty, which is based on a global science map in form of the CWTS microfield classification underlying the Leiden Ranking. We present an initial comparative analysis of the results and lay out our next steps that will involve engaging with domain experts to examine how the algorithmically identified topics relate to understandings of topics and topical perspectives that operate within this research specialty.

Introduction

While algorithms and their application to extract topical structures from bibliometric data proliferate, there is a shortage of studies that validate their results and contribute to a deeper understanding of the variation in topical structures that these algorithmic approaches create. So far only a small set of studies exists that systematically investigate the validity of solutions obtained and the difference made by alternative choices (see e.g. Haunschild et al. 2018, Sjögårde 2018, Klavans & Boyack 2017, Velden et al. 2017, Šubelj et al 2016, Boyack & Klavans 2010, Klavans & Boyack 2011, Shibata et al. 2009). We are concerned that failure to invest into the systematic comparisons and careful validation of the interpretation of algorithmically extracted topical structures undermines our ability to provide robust interpretations of their results and sound guidance on the choice and appropriate use of algorithmic topic extraction or field classification approaches. This study is a contribution to what we conceive of as a larger, much needed, research program. This program should address, on the one hand, the question of the constructive nature of a topic extraction result, relying on decisions on dataset, data model, algorithm and its parameters (Gläser et al. 2017). On the other hand, it should address the validity of interpretations of results by examining the degree of agreement between a theoretical definition of the topic concept (Havemann et al. 2017) with the actual operationalization through the chosen approach, and by exploring their correspondence to perceptions of topical structures held by their creators "in-the-wild", the researchers themselves.

This paper is a case study that takes a closer look at the topical structures obtained when using the newly released Leiden algorithm for community detection (Traag et al. 2018) to produce a local map of the field of invasion biology. As a first step, we compare this 'internal' perspective that is based exclusively on relations in the direct citation network[1] of approx. 30,000 publications in invasion biology, with an 'external' perspective that is generated by projecting this data set of publications onto a global map of science. We use the global map that underlies the field classification of the Leiden Ranking[2] and consists of approx. 20 mio publications grouped into 4047 microfields. It has been produced by CWTS using the Smart Local Moving algorithm for community detection (Waltman & Van Eck 2013). Such an external perspective captures the embedding of publications in a field into the global network of scientific publications and is expected to highlight interdisciplinary connections to other areas of research (Boyack 2017).

Klavans and Boyack (2011) argue that under certain conditions[3] a global science map can be expected to produce a more 'accurate' map of a field than local maps can - where accuracy is measured by textual coherence of the clusters obtained. However, as Haunschild et al. (2018) found in a case study of the topic of 'overall water splitting', also global maps may fail to adequately capture research fields. In this study, given the sparseness of evidence so far, rather than dismiss the local map as less accurate per se, we keep an open mind. Our interest is to investigate the capability of either perspective, internal or external, to capture understandings of topics that operate within the research specialty of invasion biology[4]. In the following we present an initial bibliometric comparison of the results obtained with these two mapping approaches, and discuss our next steps that will involve engaging with field experts who do research in invasion biology to discuss interpretations of the results of these alternative algorithmic mappings of their field of research.

Data & Methods

In this study we use a data set that is based on a lexical query developed by researchers in invasion biology (Vaz et al. 2017) in order to capture publications belonging to their research specialty:

"Ecological invasion*" or "Biological invasion*" or "Invasion biology" or "Invasion ecology" or "Invasive species" or "Alien species" or "Introduced species" or "Non-native species" or "Nonnative species" or "Nonindigenous species" or "Non-indigenous species" or "Allochthonous species" or "Exotic species".

Using the lexical query above, 30,731 document IDs from the Web of Science database were retrieved on August 28, 2017 (Figure 1). For this set, we were able to retrieve the relevant metadata (titles, abstracts, source, publication year, document types, cited references) from the 2018 stable version of the Web of Science database hosted by the 'Kompetenzzentrum Bibliometrie' (KB). We decided to restrict the time window to the years 2000-2017[5], and the document types to article, letters and reviews. The further analysis was done using the giant

[1] Direct citation networks are a popular choice in bibliometrics for the production of global science maps, given their relative sparseness. Previous studies (Klavans & Boyack 2017, Velden et al. 2017a, Shibata et al. 2009) suggest its usefulness to extract taxonomic topic structures.

[2] http://www.leidenranking.com/

[3] "All things being equal", meaning if data source, data model, algorithm and so forth are the same. They also suggest that local maps will be less accurate in particular if boundary forces (links to concepts outside the field) are stronger than core forces.

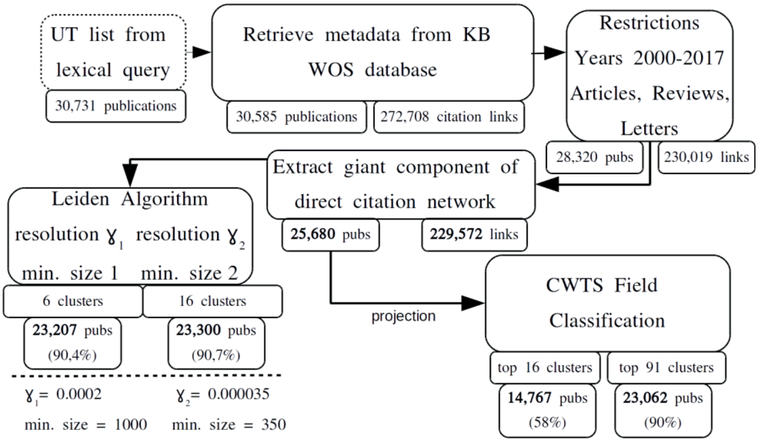
[4] Our interest in validating algorithmically generated science maps derives from theory-guided empirical work we are engaged in: M. Held is involved in the project MIMAL that explores linkages between bibliometric patterns at the micro level and the macro level; T. Velden is involved in the project 'Field specific forms of open science' that compares four fields of science and uses bibliometric maps of research specialties to support comparisons in ethnographic science studies.

[5] A specific reason for this choice was the desire to increase comparability with another bibliometric study of the field by Enders et al, (in preparation), as well as the general consideration that the field of invasion biology has experienced critical growth in the early 2000's such that the large majority of publications in the field is included in the chosen time window.

component of the direct citation network. The network of the remaining 25,680 publications and 229,572 citation links[6] served as input for the Leiden algorithm and the projection onto the CWTS microfield classification (explained below).

For clustering the direct citation network, we chose the recently released Leiden algorithm (Traag et al. 2018), a community detection algorithm which has been developed to overcome a decisive shortcoming of a widely used community detection algorithm, the Louvain algorithm (Blondel et al. 2008), namely the production of badly connected clusters. It further avoids the use of modularity as quality function due to its known shortcoming of a resolution limit and instead chooses the quality function Constant Potts Model (CPM) that has been shown to be resolution-limit free (Traag et al. 2011, 2018). For the CPM we chose two resolution values and minimum cluster sizes. Different from the methodology introduced in Waltman & Van Eck (2012), we do not merge clusters below the threshold, and instead discard them. The publications from those discarded clusters amount to less than 10% of the publications in both solutions Leiden$_6$ and Leiden$_{16}$. The algorithm was started with a random seed, run with 100 iterations with ten random starts each.

Figure 1: Schematic representation of the processing steps.



To contrast this ‘internal’ perspective of a clustering of a research specialty with an ‘external’ perspective that takes the embedding of publications in the global citation network of science into account, we project our field data set onto the CWTS microfield classification. It consist of 4047 microfields that have been extracted with the SLM algorithm on the weighted direct citation network of more than 20 million publications published in 2000-2017 and indexed by the Web of Science[7]. Of the 25,680 UTs included in the giant component, 25,627 can be found in the micro fields of the CWTS field classification. We defined as clusters in our projection cluster solution the largest intersections between our field data set and a microfield (in terms of absolute number of publications).

Finally, in order to find characteristic terms to describe the content of clusters, we extracted the noun phrases from titles and abstracts of the publications of each cluster in each cluster solution, using part of speech tagging and chunking available in the Python package ‘nltk’. Terms which had been used in the lexical query to delineate the field were excluded. To obtain a measure for how well each of the remaining terms describes the content of each cluster, we used the

[6] Following Waltman & Van Eck (2012), we produced a weighted version of the direct citation network to account for a potential variation of in citation practices within the field of invasion biology.

[7] http://www.leidenranking.com/information/fields (Accessed January 25, 2019)

differential cluster labelling by Koopman & Wang (2017), which is based on normalized mutual information (NMI). The higher the value, the more significant the term to characterize the cluster and differentiate it from the rest. For labelling the clusters in the Leiden_6 and Leiden_{16} solution, the terms of all publications from the giant component were included. In order to label the clusters in the projection solution, we only included terms and publications which occurred in the projection clusters. An additional set of labels was produced with the same approach, using journal names instead of extracted terms. The cluster labels eventually used in this paper were manually derived from those NMI score ranked lists of terms and journals by considering information provided on habitat, organisms, research problem, and the subject area of journals.

In order to visualize the relationships between the topics identified, we use topic affinity networks that evaluate the strength of citation links between clusters to determine the affinity between topics. The existence of a link between topics in the affinity network indicates a surplus of connectivity between the two topics compared to a random null model (see Velden, Yan & Lagoze 2017 for details).

Results

Topics and sizes of the 6, respectively 16 clusters in the Leiden_6 /Leiden_{16} solutions are given in the data appendix of the arXiv version of this paper[8]. An analysis of how the publications are regrouped from the six clusters of the Leiden_6 solution to the 16 clusters of the Leiden_{16} solution suggests a continuity of the overall topic structure extracted by the two clustering runs. While two topics, 'marine invasion' (Leiden_6 C3) and 'trees and pests' (Leiden_6 C5) are largely preserved, other clusters get split into smaller, refined topics. Given that the two solutions are independent and not the result of a hierarchical clustering approach, this seems noteworthy and encouraging regarding an internal consistency of results achieved with the Leiden algorithm at different levels of resolution.

Sizes and topics of some of the larger projection clusters, as well as information of the CWTS microfields that the projection clusters are embedded in are also given in the data appendix. But for a few exceptions, the projection clusters constitute only about 5% of a microfield in the CWTS classification. Adopting the terminology used by Klavans and Boyack (2011) when comparing a local and a global mapping of the field of information science, microfield m402 may be considered a 'core' microfield for invasion science (53% of its publications overlap with the invasion data set and constitute projection cluster C1 on 'invasive plants'). Three microfields may be considered 'boundary' microfields, namely m2749 (34% overlap, projection cluster C5 on 'marine aquatic invasion, ballast water, ascidians'), m1774 (17% overlap, projection cluster C2 on 'freshwater aquatic invasion, great lakes'), and m2568 (17% overlap, projection cluster C10 on 'freshwater aquatic invasion, crayfish'). All other microfields may be considered 'boundary-crossing', i.e. largely outside the field of investigation.

In Figure 2 we compare the Leiden_{16} with the projection cluster solution based on their topic affinity networks. Both solutions agree in that they include a cluster related to 'invasive plants' that consists of almost 25% of publications in the giant component. They differ in that the cluster size concentration of the projection cluster solution is lower: to cover a similar large proportion of publications from the giant component as the Leiden_{16} solution (> 90%), one has to include the 91 largest clusters of the projection cluster solution, down to a size of 37 publications. The alluvial diagram in Figure 3 shows the regrouping of publications between the Leiden_{16} solution and the 91 largest topics in the projection solution. While some topic continuity can be observed and the core of some topics clearly persists, other topics get

[8] Available online at http://arxiv.org/abs/1905.03485.

fragmented. The zoom-in in Figure 3 shows how the topics of 'marine aquatic invasion' (C2 Leiden$_{16}$) and 'ballast water' (C15 Leiden$_{16}$) split-up into numerous topics in the projection solution (these topics are located next to each other in the area of the affinity network of the projection solution circled in Figure 2). We offer two observations: first, a technical one, namely that our labelling procedure fails to extract hints of organisms or research angle when cluster sizes fall below about 100 documents (see labels in Fig. 3 for C54, C56 or C58). Second, the refinement of topics often seems driven by a focus on a specific organism: crab, algae, oyster, jellyfish, etc. Occasionally, it is driven by a specific habitat: Mediterranean, Suez canal, Antarctica.

Discussion & Future Work

The alternative internal and external mappings in this paper provide two perspectives onto the topical structure of the field of invasion biology. Common feature of those topical structures is the concentration of almost 25% of publications in a topic relating to invasive plants. This is in alignment with statements by experts that suggest that observational studies of terrestrial plants dominate the empirical literature in the field (Jeschke & Heger 2018, p. 162). Further, organisms and habitat seem to constitute important dimensions for delineating topics - likely not a surprising observation for a domain expert. Notable exceptions are the projection based topics on 'genetic diversity' (C12), and 'models, climate change' (C7) that seem rather method or research angle-driven.

The projection of the invasion biology data set onto microfields of the global map promises insights into links between topics in invasion science to neighbouring fields. However, it suffers from an enormous spread. One third of publications are represented by 'invasive plants' as a core topic and three aquatic invasion-related boundary topics. The remaining ⅔ of publications are associated with and embedded in hundreds of different microfields with each less than a 10% share. This spread of invasion biology publications across microfields suggests that a delineation and representation of the research field of invasion biology through selection of a microfield from the global map might be ill-conceived - given one trusts the lexical query used by us and by Vaz et al. (2017) to delineate the field of invasion biology. This aligns with the finding by Haunschild et al. (2018) on the field of overall water splitting. The question what these microfields are representative of and their role as a topical context for research in a research specialty such as invasion biology, deserves further investigation.

Before moving on, we plan to improve our labelling approach by implementing entity recognition of taxonomic species. This way we expect to increase the meaningfulness and precision of the content labels we extract, allowing us e.g. to contrast the content of the projection clusters with the other publications in the microfield they are embedded in.

The next major step in our study will be to explore in interviews and informal discussions with domain experts from the field of invasion biology as well as through ethnographic observations in an ongoing study, the relationship between the topic structures constructed by the chosen algorithmic approaches with the lived experience of researchers in the field of invasion biology. Specifically, we plan to pursue the following avenues:

1. How do individual research group leaders' research trails (Gläser & Laudel 2015) relate to the topical structures of the Leiden$_{16}$ and projection solutions? Do research topics that can be delineated within those trails align with or transcend the field topics we have constructed algorithmically?
2. Existing, theoretical work on empirical evidence in the field of invasion biology identifies theoretical work on key hypothesis of the field as well as empirical studies

that support or challenge those hypotheses[9]. This offers the opportunity to relate the topical structures we have generated to relevant topical perspectives generated from within the field and discuss these relations with domain experts.

Conclusions

We report first results on a comparison of an internal and an external mapping of topical structures in the research specialty of invasion biology. Both maps exhibit some common features, like the importance of work on invasive plants, and the relevance of concepts of habitat and organism for distinguishing topics. The next step in the study will be dedicated to relating the algorithmically identified topic structures to topical concepts emerging from social and theoretical processes within the research specialty.

Abstract

The electronic availability of the full-text of scholarly publications has made possible large-scale analysis of in-text citations. Many such studies have made use of signal terms—individual words or phrases that suggest some phenomenon of interest. Most studies utilizing signal terms treat them as having stable meaning; however, the usage and meaning of these terms may differ between rhetorical contexts. We conducted a preliminary analysis to investigate the extent to which the usage and semantics of *hedging* signal terms differed between the introduction, methodology, and discussion sections of scientific papers. We sampled three million sentences containing citations from a large database of full-text publications and counted the occurrences of sixteen hedging terms in each section. We found that the incidence of hedges varied across sections with distinct patterns for individual terms. We modelled semantic relationships within a section using word2vec and constructed rudimentary measures to compare the similarity of hedging terms between models trained on each section. We observed that the meaning of hedging terms differed between sections with distinct patterns for individual terms. Our results suggest that signal terms are not independent of their context which has implications for bibliometric full-text analysis.

Introduction

For more than 40 years, sociologists and information scientists have worked towards a better understanding of the function of citations (Moravcsik & Murugesan, 1975; Cronin, 1981; Small, 2004). Early analyses, while insightful, were limited by the lack of accessible data (i.e. electronic journals) and computational tools. However, the increased ubiquity of digital scholarly publications and availably of large-scale databases has made possible sophisticated textual analyses of in-text citations. Some analyses attempted to characterize the contextual attributes of in-text citations, such as their position and distribution within publications (Bertin et al., 2016a; Boyack et al., 2018). Others instead sought to develop machine learning algorithms to automatically classify *citances* (sentences containing citations) according to their function (Teufel, Siddharthan, & Tidhar, 2006), sentiment (Catalini, Lacetera, & Oettl, 2015; Jha et al., 2017), importance (Valenzuela, Ha, & Etzioni, 2015) and more.

A common input feature for citation classifiers is the presence of *signal terms* within a citance. For example, the terms "excellent" and "poor" may prove useful for the task of citation sentiment classification. Other papers have made use of specific dictionaries of signal terms to study more abstract concepts: for example, Small et al., (2017) uses a list of "discovery" terms to track scientific discoveries, whereas Chen et al., (2018) identifies terms that suggest uncertainty. A paper by Di Marco and Mercer (2004) described how a certain type of signal term—*hedges*—might be used to classify citations; however, they also noted how the semantic meaning and usage of hedging terms might differ between sections of a paper. This speaks to a wider issue with the use of signal terms in bibliometric analysis and classification: rhetorical context matters. The meaning or usage of a hedging, discovery, or uncertainty signal term may differ depending on whether the term appears in the introduction, methodology, or discussion. A term is not independent of its context (Bertin et al., 2016b).

In this paper we present a preliminary analysis of the extent to which the incidence and semantic meaning of common signal terms differ between rhetorical contexts of a manuscript. We focus on a particular type of signal term: *hedging* as defined by Hyland (1996), discussed by Di Marco and Mercer (2004), and used in Chen et al. (2018). We consider three distinct rhetorical contexts: the introduction, methodology, and discussion sections. This analysis will inform future textual analyses of scientific publications and establish a foundation for further investigations into how semantics differ between rhetorical and scientific contexts.

Data and Methods

We used data from the Elsevier ScienceDirect database, obtained and managed by the *Centre for Science and Technology Studies* at Leiden University. This data contains full-text for nearly five million English-language full-length articles, short communications, and review articles published between 1980 and 2016. More information about this dataset, including a comparison to the existing PubMed dataset, and a descriptive analysis, can be found in Boyack et al. (2018).

We first sampled 300,000 full-length English-language articles that were published after 2014. From these publications, we sampled approximately one million citances (citation sentences) listed in a section with a name that included the substring "intro"; we repeated this sampling for citances in sections with titles containing the substrings "method" and "discussion" resulting in three corpora. We tokenized sentences within each of these corpora into unigrams and bigrams and tallied the counts and proportions of each token.

We represented the semantic relationships between terms in each corpus using word2vec, a method of training vector space word embeddings from a corpus of text (Mikolov et al., 2013). Each trained word vector represents a single word; words with similar contexts will have high cosine similarities. For example, "researcher" would likely have a similar context as "scientist", and "scholar" and so their vectors would have high cosine similarities. We trained separate word2vec models for each corpus using *genism v3.6.0*. We adhered to the same training parameters as Chen et al., (2018), though we decreased the number of training vectors from 200 to 100 due to our smaller training data; we constructed selective models by including only terms that occur at least 100 times in the corpus.

To compare the meaning of a target term between word2vec models, we need a measure of similarity between models. However, due to the stochastic nature of word2vec training, direct comparison of word vectors between models is essentially meaningless, even when trained on the same data. Some researchers have developed techniques to compare models, but there is little consensus on appropriate technique (Kutuzov, 2018).

We considered two approaches to assess the similarity of a target word's semantic meaning between models. The first approach leverages *global* relationships between the target word and a large sample of words shared between the two models. For two word2vec models we defined their shared common vocabulary. We then measured the cosine similarity between the target term and each word in the shared vocabulary. We used the squared correlation between these two sets of similarities as a measure of semantic similarity. As an additional validity check we trained two word2vec models on an identical corpus of 200,000 abstracts and calculated their global semantic similarity. The smallest value of the 16 hedging terms was 0.983 with a mean of 0.992. That the correlation was high between two word2vec models trained on the same data suggests that this measure of global similarity is relatively robust.

For the second approach we examined only *local* relationships between the target term and a small list of similar words. For a target term, we selected a small number of the most similar words from the introduction word2vec model. We then compared the rankings of these words to the corresponding rankings of the target word in the methods and discussion word2vec models. We created an ad-hoc measure of change in total ranking by dividing the change in rankings between each model by the position of the word in the introduction model similarity list; this index downweighs terms appearing lower in the ranking list. Interpretation of this model's results is less straightforward than for global semantic similarity, but it provides insight into the particular relationships of individual terms.

Results and Discussion

We first assessed the extent to which the incidence of hedging phrases differed across citances by section of scientific articles. Figure 1 shows the counts of the stemmed version of each term within the introduction, methods, and discussion sections. Overall, more hedging terms were used in paper's discussion sections than in either the introduction or methods sections. This difference likely resulted from the rhetorical characteristics inherent to each section, rather than other confounding factors: the total number of citances sampled for the three sections was approximately equal. Moreover, the average number of tokens for a citance in each section differed by at most two tokens (around 28 tokens for methods, and 30 for discussion section).

Whereas hedging tended to be most common in the discussion, perhaps due to the section's typically speculative nature, we also observed differences at the level of individual terms. The most common hedges such as "should", 'may", "indicate", and "might" largely appeared in the discussion section. However, "will" was primarily used in the introduction, whereas "predict" was instead more often used in the methodology. There were also differences in the usage of words between the introduction and methodology: the usage of "should", "must', and "cannot", was roughly similar between the two sections. These findings speak to the heterogeneity of hedging terms—usage of individual terms differed by section.

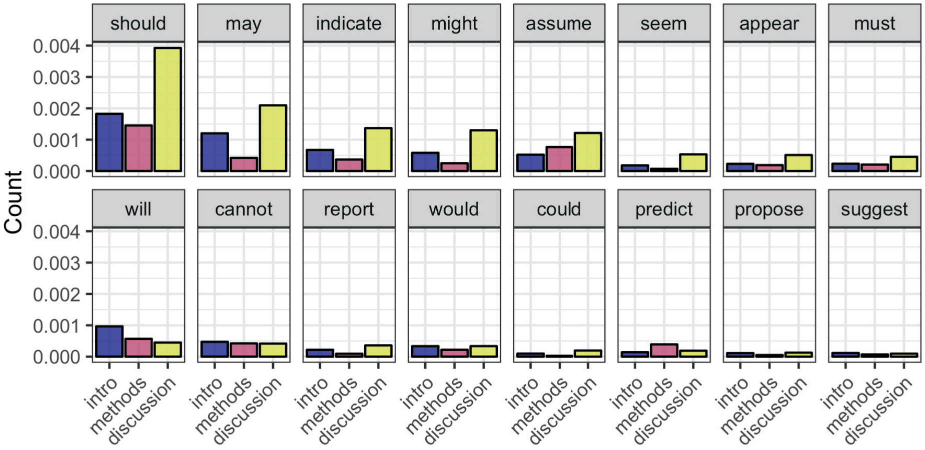

Figure 1. Counts of hedging terms appearing in the introduction, methods, and discussion corpuses. Each corpus includes approximately one million citances. Terms are arranged in order of total instances. These counts include the stemmed version of each term; for example, the count for "indicate" also includes the counts for terms such as "indicates" and "indicated".

In addition to differences in incidence, so too might the *semantic meaning* of individual hedging terms differ by section. For example, "predict" might be used in an introduction to establish a hypothesis: "we predict that *x* is related to *y*". However, in the methods section, this term may instead be used in a more technical context: "we used linear regression to predict *y* given *x*"; in this case, the meaning of the word no longer serves as a hedge in the methodology.

We modelled the semantic meaning of terms by training word2vec models for each section. We investigated the extent to which the semantic meaning of each hedging term differed between each section by calculating an ad-hoc measure of global semantic similarity for each hedging term, and between every combination of two models (Figure 2). We found that, overall, the usage of almost all hedging terms was most similar between the introduction and discussion sections and tended to be least similar between the methodology and discussion sections. Generally, the semantic meaning of hedging terms was similar between the introduction and methods and between the methods and discussion sections.

As in our analysis of the incidence of hedging we also observed heterogeneity in patterns of semantic similarity by individual terms. For example, the term “may” exemplified the general trend of high similarity between the introduction and discussion, but low similarity between these and the methodology section; however, the terms “must”, “indicate”, and “propose” ran counter to this trend. Model comparisons for the term “must” showed a similar trend as “may”, though with a much higher degree of similarity between the methodology and other sections. The semantic similarity of the term “indicate” was instead roughly similar between the introduction and methods, as well as between the introduction and discussion. The term “propose” presented a clear contrast to all other hedging terms, such that the highest semantic similarity was observed between the introduction and methodology sections. This analysis provides evidence that the semantic similarity of hedging differed between sections, and that these patterns of similarity were heterogeneous across individual hedging terms.

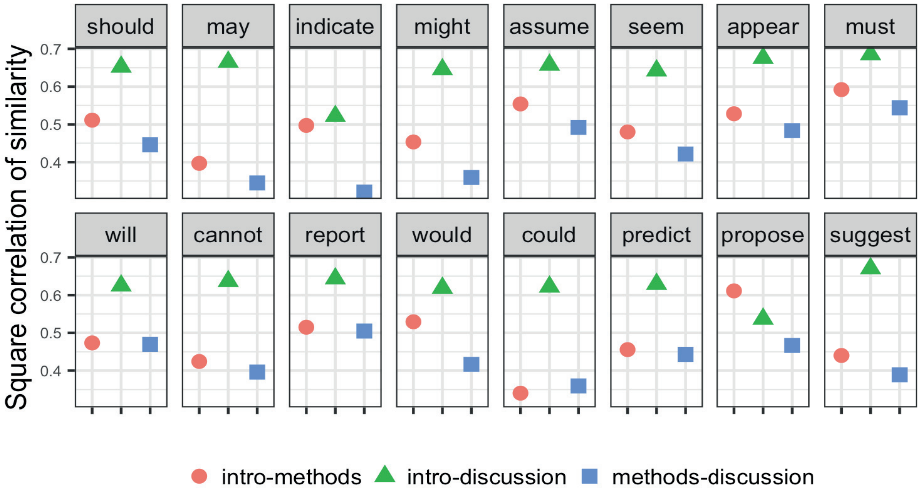

Figure 2. Global term similarity between each hedging term and for each combination of word2vec models. Global term similarity is defined as the adjusted R^2 of the line of best for the top 100,000 most common words shared between both models.

One limitation of this analysis of semantic similarity was that it relies on a measure of *global* semantic similarity, that is, the similarity between a target term and thousands of terms in the shared vocabulary between two models. This measure weighs similarities equally between a target word and all terms in the shared vocabulary. However, a small vocabulary of the most similar words may prove more useful for determining semantic similarity. For example, if we compared the semantic meaning of “dog” across two models, we would be more interested its similarity to “animal” and “pet” than its similarity to “computer”. A natural approach is to assess semantic similarity of terms at the *local level*—that is, for a select list of the top *n* most similar terms. Following this approach, we identified the top fifteen most similar terms from the introduction model and traced their change in rankings across the methodology and discussion sections. For this preliminary analysis, we only considered three hedging terms: “indicate”, “must”, and “propose”, each of which exhibited distinct patterns of similarity between the three models. The results of this analysis are shown in table 1.

From this small vocabulary, we observed a mix of both similar and divergent patterns of similarity to those observed in figure 2. Using our global measure of semantic similarity, we found that the term “must” was similar between all three models—here, we also found that “must” had the smallest total change in rankings between the introduction and other models. Moreover, the total change was smaller for the discussion section than for the methods section, potentially corresponding to the higher similarity observed between the introduction and discussion models from figure 2. However, for the term “indicate” we observed roughly similar total changes in rankings between the introduction and methods and discussion models. “Indicate”, with three terms missing in the methods model, also highlights an issue with comparisons between word2vec models—certain terms were excluded because they did not meet the minimum inclusion threshold of 100 instances. Whereas the patterns observed for “indicate” contrasted with our findings from figure 2, those for “propose” were supportive: the total change in rankings terms for the methods model was smaller than the total for the discussion model, though we note that both were especially large compared to other signal terms. One potential explanation for these large changes in rankings may be that “propose” was relatively rare in each corpus. Regardless of comparisons with figure 2, table 1 shows that, even at the local level, the semantics of hedges were heterogeneous between sections.

Table 1. Rank and change-in-rank of three selected hedging terms. For each term, this table lists the top 15 most similar words in the word2vec model trained on introduction citances, measured by cosine similarity. For each term we included the change in rank of each of the 15 similar words between the introduction word2vec model, and the methods (Met) and discussion (Dis) models. Terms not included in a model’s vocabulary are assigned a value of “-”. An ad-hoc change index—the sum of the absolute values of the change in rank, divided by the rank of the term within the introduction model–is shown at the bottom of the table.

Conclusion

With this preliminary analysis we found evidence that hedging was not independent of its position within a publication. We observed that hedging terms were more common in the discussion sections of papers, though patterns varied by individual term. We also found evidence that the semantic meaning of hedging terms differed between sections; overall, hedging was most common between the introduction and discussion though distinct patterns were observed for individual terms. We found evidence of this heterogeneity using two distinct approaches. These findings confirm discussions by Di Marco and Mercer (2004) and have direct implications for any study utilizing dictionaries of hedges or other signal terms. These findings also demonstrate that the meaning of a word cannot be fully understood when decontextualized from its context, and that the contextual factors should be considered during textual analysis of scientific publications. The results of this analysis are subject to several limitations. The most important avenue for future research is to further validate our measure of semantic similarity between models and develop more sophisticated techniques. Additionally, this analysis is limited by a relatively small sample of data—one million citances per section—which while large, falls short of the corpus sizes typically used when training more robust word2vec models. Expanding the data size may address some of the issues of terms missing from model's shared vocabulary. Future work will attempt to address these limitations while expanding the scope of analysis to include additional sections (e.g., conclusion, abstract), to distinguish between the semantic meaning of hedging between disciplines, and to examine other common signal terms, such as terms indicating uncertainty (Chen et al., 2018) and discovery (Small et al., 2017).

Abstract

Knowledge production increasingly relies on mobility. However, its role as a mechanism for knowledge recombination and dissemination remains largely unknown. Based on 1,244,080 Web of Science publications from 1,435,729 authors that we used to construct a panel dataset, we study the impact of inter-regional publishing and scientists' mobility in fostering the workforce composition of European countries during 2008-2017. Specifically, we collect information on scientists who have published in one region and then published elsewhere, and explore some determinants of regional and international mobility. Preliminary findings suggest that while talent pools of researchers are increasingly international, their movements seem to be steered by geographical structures. Future research will investigate the impact of mobility on the regional structure of scientific fields by accounting for the appearance and disappearance of research topics over time.

Background

After Europe's enlargement in 2004, a growing number of scholars had the opportunity to collaborate and live unconstrained by national borders. Some estimates indicate for instance that in 2010 there were about 1.59 million full-time researchers in the EU27 and that the number of researchers in the active population is increasing (See, for instance, More2 final report "Support for continued data collection and analysis concerning mobility patterns and career paths of researchers"). As national science systems become more globalized, they also become more dependent on the movement of researchers. This movement has been thought to be a driver of innovation and scientific breakthroughs, especially in receiving locations (Ganguli, 2015; Stephan & Levin, 2001).

However, one aspect of scientific mobility has been relatively neglected, namely, the mobility patterns of researchers across regional borders in Europe. As a result, the inter-regional structure of scientific mobility flows is still poorly understood. Yet, scholarly knowledge exchanges based on workforce mobility are vital to the transfer of tacit knowledge that cannot be transferred through formal communication channels (e.g., research articles, journals, books, e-mails) (Gertler, 2003). When mobile scholars move, they bring information and know-how, skills, and ideas that differ from natives and that are essential for knowledge recombination, interactive learning, and novelty. Based on previous theoretical and empirical work (e.g., Agrawal et al., 2006; Jaffe et al., 1993) we hypothesize that mobility is an effective mechanism for disseminating knowledge and capabilities across research institutions, fields and locations and is therefore important to our understanding of how fields evolve over time. Previous studies already point in that direction. Moser et al. (2014) showed that German-Jewish scientists fleeing from Nazi Germany into the US played a central role in the emergence of new chemistry sub-fields in which incumbents also participated. Ganguli (2015) showed that, after the 1991 breakdown of the Soviet Union, Russian scientists who migrated to the US were much more cited by US scientists than those who did not migrate. In a large-scale study of the Web of Science database, Sugimoto et al. (2017) found that scholars who were mobile (i.e., more than one affiliation to different countries) have approximately 40% more citations than non-mobile scholars.

Three exploratory questions will be asked at this preliminary stage: (1) How is scientific mobility distributed across European regions? (2) To what extent are international and regional mobility related? (3) Which regional mobility network patterns can be seen across countries? To answer these questions, we use Web of Science publications to construct a longitudinal data set for 264 regions from 32 European countries. In this research-in-progress paper, we briefly discuss the methodology, describe the data and discuss the preliminary findings and our plans for future research.

The data

Both publication data and regional data are used to compute regional mobility. Specifically, we reconstruct career trajectories of 1,435,729 distinct authors based on 1,244,080 publications (articles and reviews) published between 2008 and 2017. These data were collected from the CWTS in-house version of the Web of Science provided by Clarivate Analytics. Authors' profiles were isolated using the author-disambiguation algorithm developed by Caron and van Eck (2014). Since there is no consistent method for tracking scientific mobility, and categories of highly skilled workers are often too ambiguous to identify specific groups of scientists, we use author affiliations available in scientific publications. This is used to determine who moved between European regions, where and in what year. For each author we assign their affiliation addresses to the NUTS ('Nomenclature of Territorial Units for Statistics') classification structure, provided by Eurostat[1]. European countries differ in terms of size, population, number of researchers, availability of funding, and number of universities, therefore, we carry out the analysis at the regional level. We focus on regions with an average of at least 50 publications per year resulting in 264 NUTS2 European regions from 32 countries – EU-28 plus Norway, Iceland, Switzerland, and Turkey.

Following on Robinson-Garcia et al. (2019) we define mobile scientists as those who have affiliations in at least two different regions either simultaneously (dual affiliation) or over the period of analysis (i.e., published in more than one region between 2008 and 2017). Accordingly, the dataset consists of 1,435,729 authors out of which about 14% (203,925) have published in more than one region. The mobility of scholars across regions is quantified by observed changes (movements) in the reported affiliation and corresponding region as stated by the scholars themselves in publication documents.

Preliminary evidence

How is scientific mobility distributed across European regions?

We here present preliminary evidence on regional mobility. A total 44% of scholars' movements involves NUTS2 regions belonging to the same country (regional mobility), while 55% of remaining movements involves international mobility. With respect to the distribution of movements of scholars across the European geography, 61 regions – out of 264 – concentrate 67% of scientists' movements. The countries with the highest numbers of mobile researchers are depicted in Figure 1. It follows that mobility flows of scholars tend to be clustered regionally within Europe. The regions in which we find heavy movement, such as Île-de-France, were also those where mobile researchers tended to locate more generally. Mobile researchers are noticeably absent from Eastern European regions, as these locations were also less likely to have lower scientific activity and lower levels of research funding.

[1] https://ec.europa.eu/eurostat/web/nuts/background

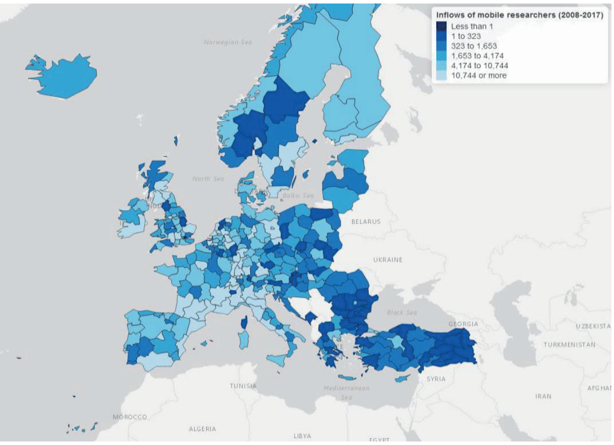

Figure 1. Total mobility inflows of scientists are shown for NUTS2 regions. In the map, lighter colours represent larger inflows.

To what extent are international and regional mobility related?

Table 1 shows the shares of internationally mobile and regionally mobile researchers in Europe's top ten countries ranked by the share of mobile researchers in each country. As can be seen, the shares of international mobility and regional mobility are significantly different. All countries have higher shares of internationally mobile researchers than regionally mobile researchers.

Table 1. Share of internationally and regionally mobile researchers for the top 10 countries with the highest share of mobile researchers (2008-2017).

Country	*%* *mobility*	*%* *international mobility*	*%* *regional mobility*	*#* *regions*
1. Switzerland	31%	25%	6%	7
2. Netherlands	28%	19%	10%	12
3. Belgium	27%	19%	8%	11
4. Germany	26%	15%	11%	38
5. Italy	26%	16%	9%	21
6. Sweden	25%	20%	5%	8
7. Austria	25%	21%	4%	9
8. United Kingdom	24%	15%	10%	40
9. France	23%	14%	8%	27
10. Spain	23%	15%	7%	18

The top countries in the table are also high-income countries separated by relatively short distances, making it easier for researchers to internationalize in those countries. Switzerland has the highest share of mobile researchers (31%), with 25% of mobile scholars having affiliations in at least two countries (internationally mobile) and 6% in at least two regions of Switzerland (regionally mobile). France (23%) and Spain (23%) have the lowest shares of mobile researchers. Switzerland has the highest share of internationally mobile scholars (25%) compared to other countries, whereas Germany (15%), the United Kingdom (15%), Spain (15%), and France (14%) have the lowest share. This can be explained in part by the number and size of these countries' regions (See Figure 2, right panel). France, for example, has more regions (n=27) than Switzerland (n=7) that are larger in spatial scale and scientific workforce. Such conditions may offer researchers a more diverse set of options and point to the role of geography in facilitating and/or constraining scientific mobility.

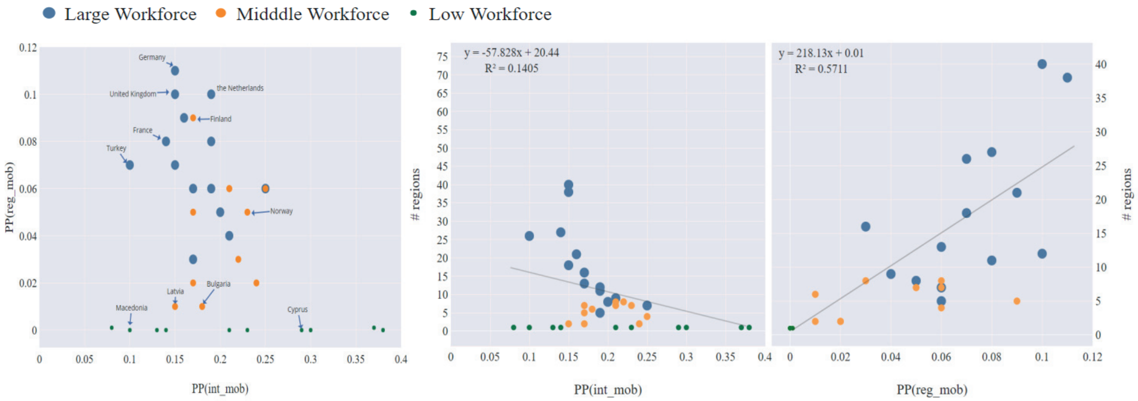

Figure 2. Scatterplots of proportion of regional mobility and international mobility by country (2008-2017). Categories are based on country's workforce size (i.e. overall scholars identified in WoS).

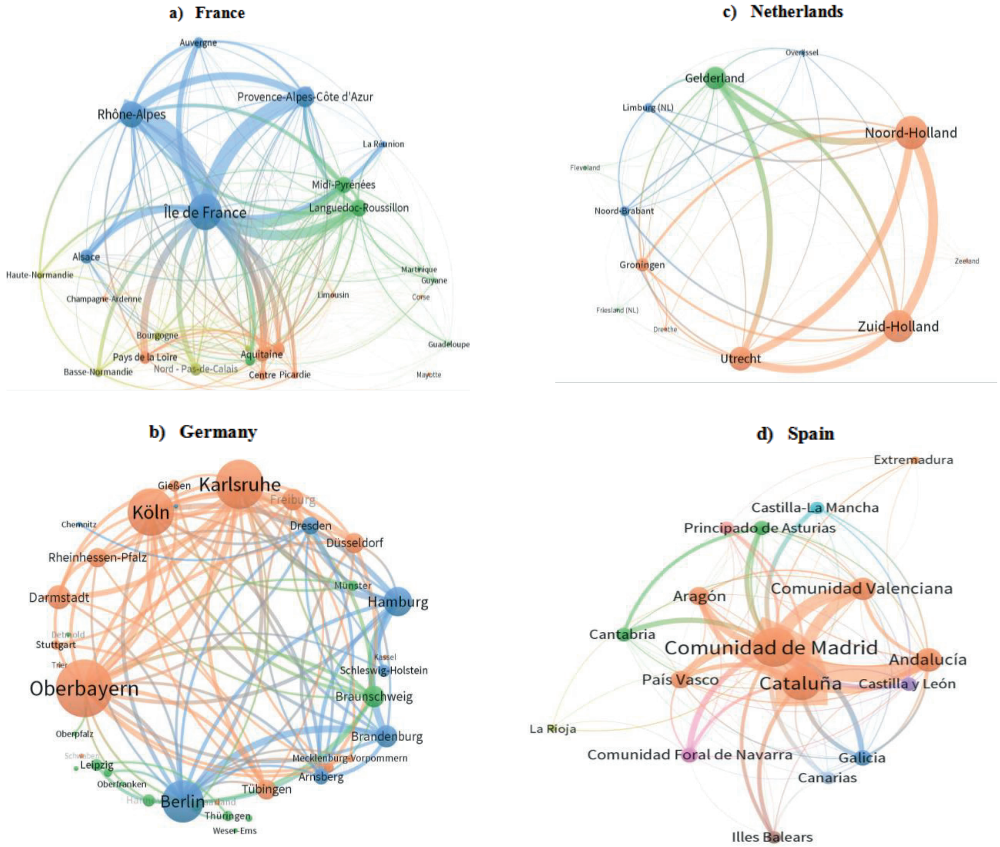

Figure 3. Undirected network of regional mobility flows for Germany, Spain, France and the Netherlands (2008-2017). The network visualizations were created using the VOSviewer software (van Eck & Waltman, 2010).

The left panel of Figure 2 suggests that there is no clear relationship between the proportion of scholars who are regionally mobile and scholars who are internationally mobile. The size of countries' workforce (as measured by the total number of scholars publishing in the WoS and identified in the countries) also does not seem to be related to the prevalence of any kind of mobility. As expected, smaller countries with few or no regions (e.g. Cyprus) also do not have any regional mobility. In fact, the two panels on the right side indicate this obvious but noteworthy pattern: larger countries with relatively high number of regions tend to have higher proportions of regional mobility (right panel). The middle panel of Figure 2 shows that larger countries with multiple regions tend to have slightly lower shares of international mobile scholars.

Which regional mobility network patterns can be seen across countries?
Figure 3 shows the regional mobility networks of four European countries: France, Netherlands, Germany, and Spain. The nodes represent the different regions in the countries, the size of the nodes is determined by the total number of mobile scholars affiliated with the region, and edges are established by the number of common scholars that have been affiliated to each pair of regions. Although a thorough network analysis is not performed here, the graphs point to two main patterns. Firstly, a concentrated pattern (e.g., France and Spain), in which a few regions (e.g., Ile de France in France and Madrid and Cataluña in Spain) conform strong nodes, having multiple mobility linkages with the other regions in the country. Secondly, a more distributed pattern (e.g. Germany and the Netherlands), in which there are more diverse connected regional nodes (e.g. Oberbayern, Berlin, Köln, Karlsruhe and Hamburg in Germany; and Noord-Holland, Zuid-Holland, Utrecht and Gelderland in the Netherlands), without clearly dominant nodes. Some proximity patterns can also be seen in some of the networks such as the stronger linkages among the northern Spain regions (e.g., Cantabria and Asturias) or among regions in the Randstad area of the Netherlands (e.g., Zuid-Holland, North-Holland and Utrecht). The fact that different networks show very different mobility patterns suggests that national scientific systems in Europe can be organized differently.

Conclusion and future research

In this paper, we have presented a first attempt to study mobility patterns among European regions using bibliometric methods. As a proof of concept, it can be concluded that regional mobility is also traceable by bibliometric means. Our preliminary results suggest that mobility patterns between regions differ from mobility patterns between countries (Robinson-Garcia et al., 2019), since they have different incidence across countries. Results indicate that, there is an unequal distribution of regionally mobile scholars across European countries. Moreover, national regional mobility does not seem to have a strong relationship with the level of international mobility of the country. Another conclusion is that, there are two important factors in the consideration of regional mobility: the existence of a regional geographical structure in the country (otherwise regional mobility is not possible), and the existence of a sizeable workforce in the country.

Overall, our results point that regional mobility is a social phenomenon that deserves attention by itself. Thus, these initial observations motivate us to examine the consequences of mobility for the distribution of scientific portfolios (i.e., thematic delineation of regions). As the inflow of researchers into regions is also likely to generate a positive effect on the scientific innovation in receiving locations, we will test whether knowledge generated by scholars in their origin location affects the scientific portfolios of their new location over the years.

We ask, therefore, two interrelated questions: What is the effect of the influx of mobile scientists on the emergence of scientific fields of receiving regions? How stable is the network of inter-regional mobility flows? We will use this approach to identify co-location effects driven by inter-regional publishing. Our expectation is that the international and regional movement of scholars can explain differences in scientific portfolios in European regions. This will include studying the inflow and outflow dynamics of regions in attracting (or sending) scholars; as well as controlling for other demographic aspects such as age and gender of these regionally mobile scholars.

Finally, similar to the identification of internationally mobile researchers by Robinson-Garcia et al. (2019), this study is dependent on the number of publications to identify mobility patterns, the coverage of the database used to extract the publication data, and the completeness of the author-affiliation information. To minimize the influence of these biases, we are currently expanding the methodology to include other document types such as conference publications, book reviews, and letters, and comparing mobility statistics derived from publication data from the Web of Science with highly skilled migration statistics.

Acknowledgements

We thank Alfredo Yegros and Wout Lamers for their help in assigning affiliation addresses to the NUTS2 regional classification. This research is partially funded by the South African DST-NRF Centre of Excellence in Scientometrics and Science, Technology and Innovation Policy (SciSTIP) and by the European Commission DG EAC, U-Multirank project.

Does Monetary Support Increase Citation Impact of Scholarly Papers?

Abstract

One of the main indicators of scientific development of a given country is the number of papers published in high impact scholarly journals. Many countries introduced performance-based research funding systems (PRFSs) to create a more competitive environment where prolific researchers get rewarded with subsidies to increase both the quantity and quality of papers. Yet, subsidies do not always function as a leverage to improve the citation impact of scholarly papers. This paper investigates the effect of the publication support system of Turkey (TR) on the citation impact of papers authored by Turkish researchers. Based on a stratified probabilistic sample of 4,521 TR-addressed papers, it compares the number of citations to determine if supported papers were cited more often than those of not supported ones, and if they were published in journals with relatively higher citation impact in terms of journal impact factors, article influence scores and quartiles. Both supported and not supported papers received comparable number of citations per paper, and were published in journals with similar citation impact values. Findings suggest that subsidies do not seem to be an effective incentive to improve the quality of scholarly papers. Such support programs should therefore be reconsidered.

Introduction

The number of refereed papers that appears in scientific journals along with citations thereto is considered to be the main indicators of scientific productivity and quality of a given researcher, a research organization or a country. Many countries introduced what is called performance-based research funding systems (PRFSs) to streamline the scientific production process and improve the research performance (Jonkers & Zacharewicz, 2016).

PRFSs aim to assess the performances of researchers in a given time period. Some countries provide monetary incentives directly to the researchers in the form "piece rates" or "cash-for-publication" schemes (Heywood, Wei, & Ye, 2011) while others prefer to reward researchers' organizations by allocating funds to them (De Boer et al., 2015). Both "ex ante" and "ex post" assessments are being used for this purpose. Compared with peer review (which requires labor-intensive evaluation processes prior to funding allocation), it is relatively easier, and less costly, to carry out ex post quantitative assessments on the basis of bibliometric measures.

Notwithstanding the type of assessment carried out, research organizations or countries tend to eagerly incentivize their researchers because they in turn expect return on investment (RoI), usually as an increase in the number of papers published by their researchers as well as the citation impact of their papers. However, such monetary incentives do not necessarily produce the intended outcomes, as the existence of PRFSs does not correlate well with the research productivity or quality (Auranen & Nieminen, 2010). The effect of PRFSs on the increase in the quantity of publications is "temporary and fades away after a few years" while the average effect on the quality of publications is "nil" (Checchi, Malgarini, & Sarlo, 2019, pp. 45, 59).

This paper aims to study the effect of the publication support system of the Turkish Scientific and Technological Research Council (TÜBİTAK) on the increase of the citation impact of papers published in scientific journals. The support system is based on the concept of "cash-for-publication" and has been in place since 1993. The authors of papers get rewarded on the basis of Journal Impact Factors (JIFs) and, more recently, Article Influence Scores (AISs) of journals in which their papers are published. The higher the JIF values, the more money the authors get paid, with a cap of 7,500 Turkish Lira (circa 3,000USD in 2015). We compare all papers published between 2006 and 2015 and indexed in Web of Science (WoS) with at least one author whose address is based in Turkey (henceforth "TR-addressed papers") with those supported by TÜBİTAK to see if supported papers received more citations and if they were published in higher quality journals in terms of JIFs, AISs and quartiles (Q1 through Q4). The rest of the paper is organized as follows: The next section briefly reviews relevant studies. The Data Sources and Method section describes the data and sampling technique used to select the TR-addressed papers along with the matching algorithms written to identify the supported ones. The Findings and Discussion section presents detailed findings. The paper ends with Concluding Remarks.

Literature Review

Performance-based research funding systems (PRFS) came into being in 1980s. The Research Excellence Framework (REF) of UK is one of the oldest PRFSs based on peer review and has been in use since 1986 (De Boer et al., 2015, p. 113). Yet, bibliometric measures such as JIF have become the dominant method used for research evaluation purposes within the last two decades and they are readily available through Journal Citation Reports (JCR) published annually by Clarivate Analytics.

Several countries have developed primarily JIF-based PRFS where JIF values are used (sometimes in combination with peer review) to determine the amount of monetary support per paper. The PRFS use around the world has been reviewed in a number of studies (e.g., Auranen & Nieminen, 2010, De Boer et al., 2015; European Commission, 2010; Geuna & Martin, 2003; Hicks, 2012; Pajić, 2014). The practices tend to vary from country to country. Some reward researchers directly through what is called "cash-for-publication" schemes (e.g., China and Turkey) while others support the affiliated research units or universities (e.g., UK and South Africa) (Heywood, Wei, & Ye, 2011; Tonta, 2017a; De Boer et al., 2015; Harley, Huysamen, Hlungwani, & Douglas, 2016; Lee & Simon, 2018).

PRFSs tend to produce unintended consequences or "side effects" (Geuna & Martin, 2003), cause researchers to develop "opportunistic behavior" (Abramo, D'Angelo & Di Costa, 2018), and eventually become "perverse incentives" (Tomaselli, 2018). Muller (2017) studied the subsidies from the viewpoint of "rent seeking" theory in economics and explored the impact of distorted incentives on academia, academics and society at large. According to rent seeking theory, academics "compete for artificially contrived transfers" in various forms (e.g., grant funding, monetary incentives for publications and citations). These transfers are usually redirected by public institutions from social surplus to rent seeking academics on the basis of bibliometric measures that are thought to measure academic success better and "provide greater reassurance of quality" (p. 59). Such measures are therefore increasingly supplanting (rather than supporting) peer review used to judge the quality of scholarly output, and universities are "creating institutional rules and practices that actively incentivize rent-seeking behavior" (Muller, 2017, p. 61). In South Africa, for instance, the amount of monetary support per paper (which may be as high as 10,000USD per a single-authored paper) is the same, regardless of where the paper has been published as long as the outlet is "accredited" by the Department of Higher Education and Training. Thus, one can submit their work to lower quality journals with relatively lower standards of peer review in order to collect subsidies quickly and more often. This may, in turn, have created a "powerful perverse incentive" and encouraged at least some researchers to "game" with the system and produce "fraudulent –or ethically questionable– publications" (Muller, 2017, pp. 63-64). Muller (2017) underlines the dilemma of such incentives as follows:

> Under the rent seeking conceptualization of such systems, appeals to individual or institutional integrity are not likely to be successful. The system directly creates

> incentives for the activities cautioned against, undermining cultures of ethical practice, and therefore only measures that carry suitable material punishment are likely to counteract these undesirable effects. (p. 64)

The side effects of PRFSs are not limited only with researchers publishing in lower quality outlets or "seeking out 'easier' publication types" (Sīle & Vanderstraeten, 2019, p. 86). Subsidies tend to discourage types of research that require more time to carry out using novel experiments prolonging the publication process, thereby giving way to papers with little or no societal impact whatsoever (Geuna & Martin, 2003; Tonta, 2017b, pp. 27-30). Moreover, some researchers simply prefer to publish in "predatory journals" and set up what is called "citation circles" to benefit more from PRFS (Good, Vermeulen, Tiefenthaler, & Arnold, 2015; Teodorescu & Andrei, 2014, pp. 228-229). South African researchers published as much as five times more papers in predatory journals than those in the United States or Brazil did (Hedding, 2019). While the number of South African publications has doubled (as pointed out earlier) after the introduction of the subsidy program, the ones published in predatory journals increased 140 times during the same period (2004-2010) (Mouton & Valentine, 2017).

Turkey, too, has a bad reputation and ranks third (after India and Nigeria) in the world among 146 countries in terms of number of papers published in predatory journals (Demir, 2018, p. 1303). Beall's (now defunct) list of predatory journals includes 41 such journals originating from Turkey, second highest after India (Akça & Akbulut, 2018, p. 264). Although no study has so far been carried out on TR-addressed papers published in predatory journals, it is likely that several such papers have been subsidized in the past under the support program. For example, more than 80% of the subsidies for papers in anthropology in 2015 went to a single predatory journal in this field in which Turkish researchers have published a total of 127 papers, most of which had had nothing to do with anthropology (Tonta, 2017b, p. 80).

Despite the side effects and undesired outcomes of PRFSs, there appears to be a commonly held belief in research funding and research performing institutions that subsidies would increase the number of papers and their citation impact. Researchers motivated by such subsidies would produce more papers with higher quality. However, the relationship between subsidies and the increase in productivity and quality is not clear-cut (Auranen & Nieminen, 2010). While there appears to be some evidence that subsidies increase the number of papers to some extent, this is not reciprocated with a similar increase in the quality of papers in terms of their citation impact (Butler, 2003, 2004; Good et al., 2015; Osuna, Cruz-Castro, & Sanz-Menéndez, 2011). For instance, the number of South African publications has almost doubled in seven years (2004-2010) after the implementation of the subsidy system. Yet, their citation impact (number of citations per paper) has decreased steadily (Pillay, 2013, p. 2). A small-scale study carried out at the University of Cape Town after the implementation of PRFS showed that the number of output is negatively correlated with both the number of citation counts of papers and their field-weighted citation impact. Although the variance explained was relatively modest, findings indicate to some extent that greater subsidy seems to be "associated with lower citation impact," which may, in part, be due to the fact that the PRFS currently in use "does not factor in research quality and impact" (Harley et al., 2016). Similarly, the number of TR-addressed papers listed in citation indexes has increased 19-fold between 1993 (when TÜBİTAK's support program began) and 2015 (from 1,500 papers to more than 28,000) (Tonta, 2017b, p. 32). Turkey has jumped from 37th place in 1993 to 18th in 2008 in the world ranked by the number of indexed publications. Yet, findings of an interrupted time series analysis based on 390,000 TR-addressed publications listed in the WoS database between 1976 and 2015 (of which 157,000 or 40% were subsidized between 1997 and 2015) showed that the support program seems to have had no impact on the increase in the quantity of TR-addressed publications (Tonta, 2017a). Moreover, the citation impact of TR-addressed papers has constantly decreased throughout the years and is well below (40%) that of the world average of all papers (Çetinsaya, 2014, p. 127; Kamalski et al., 2017, p. 4).

It appears that PRFSs do not help much in terms of improving the quality of research and force researchers to choose between "cash or quality" (Hedding, 2019). We test this conjecture with reference to Turkey and see if the subsidy system currently in use in Turkey has improved the citation impact of TR-addressed papers by comparing the number of citations per paper, JIFs, AISs and quartiles of journals in which both supported and not supported papers were published. We present below the data sources and method used to analyze the data.

Data Sources and Method

We used the well-known bibliometric measures of number of citations per paper, JIF, AIS and JCR quartiles to compare the citation impact of supported and not supported TR-addressed papers. JIF is defined as the "average" citation impact of papers published in a given journal within a given time period. AIS takes into account five years' worth of citation data for a given journal and weights citations on the basis of JIFs. If citations come from high impact journals, they are weighted more heavily. AIS is similar to Google's PageRank algorithm in that it uses the whole JCR citation network to calculate the AIS for a given journal. Unlike JIS, AIS indicates if each article in a journal has above- or below-average influence, 1.000 being the average of all journals included in JCR's citation network (Article, 2019). AIS is more stable and can therefore be used in interdisciplinary comparisons where journals have varying publication and citation patterns, although both metrics are highly correlated (r = .9) (Arendt, 2010). JIF is used to categorize journals under at least one subject category, and journals under each subject category are divided into four quartiles based on their JIF values (the first 25% of the journals with highest JIFs constitutes Q1, the second 25% Q2, etc.).

In order to identify all TR-addressed papers published between 2006 and 2015 and indexed in Web of Science (WoS), we used the following advanced search query (December 2, 2017):

> **AD=**(Turkey OR Turquie OR Türkei OR Türkiye OR Turquia)
> **Timespan:** 2006-2015. **Indexes:** SCI-EXPANDED, SSCI, A&HCI. **PubType**: Article

We found a total of 225,923 TR-addressed papers and downloaded them. We obtained the payment information for 100,919 TR-addressed papers whose authors sought financial support from TÜBİTAK through its Support Program of International Publications (UBYT). Altogether some 44% of all papers were supported (range: 59% in 2007; 28% in 2015).

We then stratified all TR-addressed papers by year and scrambled them within each year (in case they had an inherent order by author or journal name, for example) so that certain records would not appear disproportionally in the sample. We wrote a macro to select every 12th and 75th records (these numbers were randomly chosen) out of the stratified list of all TR-addressed records (225,923). Sample size being 2% of the population, we obtained a total of 4,521 records in the sample using the stratified probability sampling technique. The sample size for each year ranged between 1.86% and 2.05%, average being 1.99% (which is quite close to 2%).

Next, we wrote a second macro to match up journal data from JCR and InCites with respective years to identify bibliometric characteristics of journals (e.g., JIF, AIS, Times Cited, Quartiles and so on) in which TR-addressed papers appeared along with the number of citations that each paper received, if any (February 2, 2018). Data were then added to all the records (seven journals did not match due to inconsistencies in journal names, which were added manually).

Finally, we wrote a third macro to match the list of papers supported by TÜBİTAK with all papers (supported or not). (Some 64 records did not match due to inconsistencies in paper titles, which were added manually.) This enabled us to compare both paper and journal characteristics for both supported and not supported papers (e.g., number of citations for papers, and JIF, AIS and quartile for journals). The matching algorithm seems to have worked quite well. Altogether, 44% of all papers were supported by TÜBİTAK. In the sample, the percentage of supported papers was somewhat lower: 1,679 out of 4,521 (or 37%). The difference (7%) is due to inconsistencies in data (such as punctuation marks and abbreviations used in titles of papers and journals). Nevertheless, we looked at the data more closely. Papers appeared in 9,463 different journal titles. The ones supported by TÜBİTAK appeared in 2,336 different journal titles. Some 2,153 journals (or 92%) were represented in the sample, of which 986 (or %42) had published at least one supported TR-addressed paper between 2006 and 2015. We do not expect such small fluctuations to have any considerable impact on the analysis that follows.

We used MS Excel and SPSS 23 for data analysis and visualization; independent samples t-test for significance, as our sample size was relatively large (4,521) (Lumley, Diehr, Emerson, & Chen, 2002); and chi-square for test of independence. We used an alpha level of .05 for all statistical tests.

Findings and Discussion

As indicated earlier, the number of papers published between 2006 and 2015 is 225,923. Table 1 and Fig. 1 provide average and median JIFs and AISs of journals in which all TR-addressed papers appeared during this period. The median JIFs range between 0.998 (2012) and 1.379 (2015) while median AISs range between 0.321 (2012) and 0.457 (2010). Close to half the papers were published in low impact journals (i.e., JIF below 1.000), and their AIS values were less than half (around or below 0.400) of that of the world average (1.000). Although there seems to be a slight increase in recent years in median JIFs and AISs of papers, this has probably more to do with the continuing increase in JIFs over the years (Fischer & Steiger, 2018).

Table 1. Average and median JIFs and AISs of journals in which all TR-addressed papers published (2006-2015)

Year	Average JIF	Average AIS	Median JIF	Median AIS
2006	1.481	0.508	1.087	0.411
2007	1.311	0.454	1.091	0.406
2008	1.444	0.536	1.098	0.403
2009	1.409	0.481	1.072	0.399
2010	1.546	0.526	1.245	0.457
2011	1.327	0.459	1.053	0.384
2012	1.401	0.455	0.998	0.321
2013	1.626	0.504	1.231	0.351
2014	1.769	0.537	1.234	0.342
2015	1.988	0.574	1.379	0.368

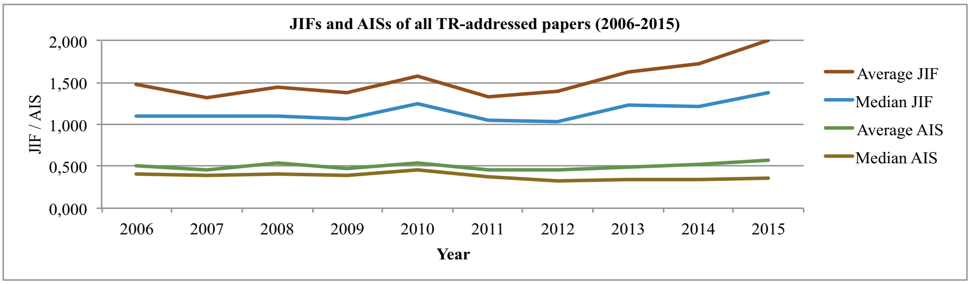

Fig. 1. Average and median JIFs and AISs of journals in which all TR-addressed papers published (2006-2015)

Findings below are based on the stratified probability sample of 4,521 papers (2006-2015). The great majority (90%) of the papers in the sample were Science papers. Social Science and Arts and Humanities papers constituted about 9% and 1% of all papers, respectively. Papers in the sample were cited a total of 55,383 times. The average number of citations per paper was 12 (*SD* = 42). Half the papers received five or fewer citations (min. = 0, max. = 2,246). Only 1% (or 45 papers) received 100 or more citations while 32% received 10 or more. Some 13% of papers were not cited at all. As expected, Science papers received the overwhelming majority of the total number of citations (over 92%) followed by Social Science papers (7%) and Arts and Humanities papers (less than 1%).[1]

Table 2 provides descriptive statistics and statistical test results for papers in the sample. As indicated earlier, 37% (1,679) of papers in the sample were supported by TÜBİTAK. Supported papers collected 43% (23,654) of all citations. On average, supported papers were cited slightly more often (M_{all} = 14.1, *SD* = 22.5) than not supported ones (M_{all} = 11.0, *SD* = 49.8). This difference was significant *t* (4,519) = -2.39, *p* < .05; however, the effect size was rather small (*r* = .04). Similarly, supported science papers were cited somewhat more frequently on average (M_{sci} = 14.5, *SD* = 22.7) than not supported ones (M_{sci} = 11.3, *SD* = 52.1). Again, although the difference was significant *t* (4,081) = -2.28, *p* < .05, the effect size was infinitesimal (*r* = .04).

Table 2. Descriptive statistics and test results

	Citation impact	Supported papers				Not supported papers				t	p	r
		N	Mdn	M	SD	N	Mdn	M	SD			
All papers	# of cit.	1679	7.0	14.1	22.5	2842	4.0	11.0	49.8	-2.39	**.02***	.04
	JIF	1624	1.2	1.6	2.3	2696	1.1	1.5	2.0	-1.07	.28	.02
	AIS	1520	.4	.5	.9	2405	.4	.5	0.9	-.39	.70	.01
Science	# of cit.	1508	7.5	14.5	22.7	2575	4.0	11.3	52.1	-2.28	**.02***	.04
	JIF	1482	1.3	1.6	2.4	2473	1.1	1.5	2.0	-1.17	.24	.02
	AIS	1388	.4	.5	.9	2218	.4	.5	.9	-.48	.63	.01
Social Science	# of cit.	171	4.0	10.6	20.1	267	3.0	8.7	13.8	-1.18	.24	.05
	JIF	142	1.2	1.3	1.0	223	1.0	1.4	1.3	-.43	.67	.02
	AIS	132	.4	.4	.3	187	.4	.5	.50	.52	.61	.03

Notes: *N*: Number of papers; *# of cit.*: Number of citations; *Mdn*: Median; *M*: Mean; *SD*: Standard Deviation; *t*: t-test; *p*: p value; *r*: effect size; *cit.*: citation; *JIF*: Journal Impact Factor; *AIS*: Article Influence Score; *: statistically significant at alpha level .05.

That during a 10-year period a supported paper in general and a supported science paper in particular received on average about three more citations than a not supported one did and that the difference was significant has probably more to do with the sample size than a true effect. This is because insubstantial differences and small effect sizes can still be significant in a relatively large sample (as is the case in this study). To put the difference into a better perspective, assuming that any given paper had on average six years to collect citations, a supported paper received about half a citation more per year than a not supported one did. This can hardly be considered a substantial difference. In fact, the statistically significant difference per paper between the numbers of citations for supported (M_{ssci} = 10.6, *SD* = 20.1) and not supported (M_{ssci} = 8.7, *SD* = 13.8) Social Science papers disappeared (*t* (436) = -1.18, *p* > .05), as Social Science papers constituted less than one tenth of all papers in the sample. Fig. 2 provides a comparative view of the number of citations per paper for all papers as well as for

[1] Note that 49 Arts and Humanities papers that received a total of 289 citations were excluded from further analysis as bibliometric characteristics of Arts and Humanities journals are not listed in JCR.

Science and Social Science papers. Boxplots show the means, medians, and first and third quartile values for both supported and not supported papers.

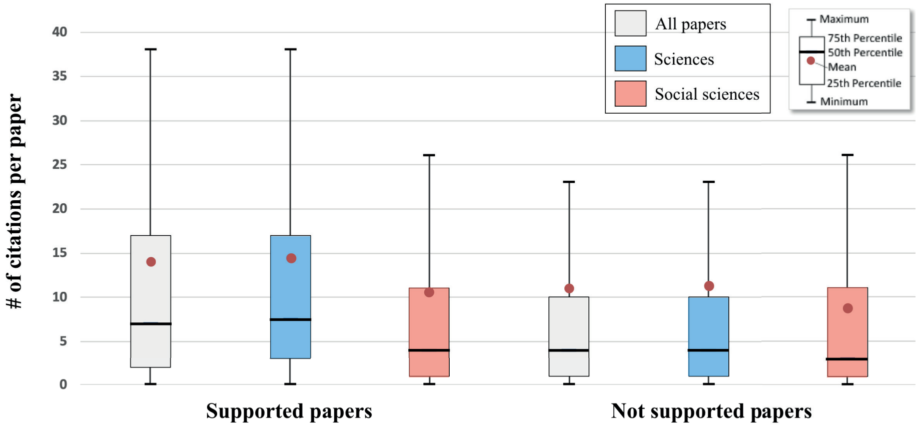

Fig. 2. Number of citations per paper for supported and not supported TR-addressed papers

Table 2 also provides data on citation impact values (e.g., JIF and AIS) of journals in which TR-addressed papers were published. On average, the JIF values of journals publishing all supported papers (M_{all} = 1.6, *SD* = 2.3), supported Science papers (M_{sci} = 1.6, *SD* = 2.4), and supported Social Science papers (M_{ssci} = 1.3, *SD* = 1.0) were quite similar to those publishing not supported ones (M_{all} = 1.5, *SD* = 2.0; M_{sci} = 1.5, *SD* = 2.0; and M_{ssci} = 1.4, *SD* = 1.3, respectively). The differences were not statistically significant in all three cases (t_{all} (4,318) = -1.07, $p > .05$; t_{sci} (3,953) = -1.17, $p > .05$; and t_{ssci} (363) = 0.41, $p > .05$, respectively). Likewise, the differences between the AIS values of supported and not supported papers were not statistically significant, either (see Table 2 for details). Fig. 3 provides the boxplots for JIF and AIS values of journals publishing both supported and not supported papers for all papers as well for Science and Social Science papers. JIF and AIS data of both supported and not supported papers were highly skewed with heavy tails, indicating that papers were mostly published in relatively mediocre or low impact journals. Average JIF and AIS values of journals obtained from the sample are consistent with those of all journals in the population (see Table 1, Fig. 1).

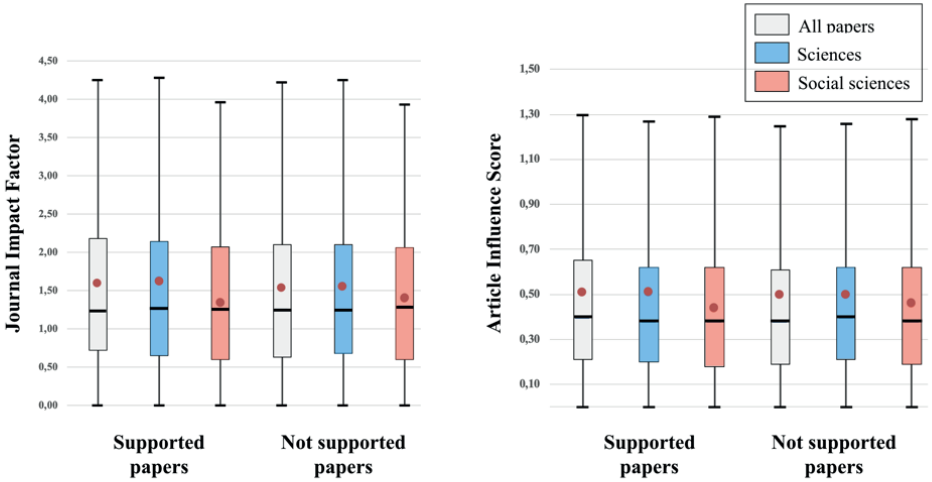

Fig. 3. Journal Impact Factors (left panel) and Articles Influence Scores (right panel) of journals publishing supported and not supported TR-addressed papers

Fig. 4 below provides the percentage distributions of JIF values of supported and not supported papers. Note that the percentages of supported and not supported papers were quite similar to each other, supporting the results of the statistical tests further. Correlation between JIF and AIS values of journals publishing TR-addressed papers was quite high (Pearson's r = .946), explaining 90% of the variance in the data[2] and confirming the findings of similar studies (e.g., Arendt, 2010). We therefore do not provide the distributions of JIF and AIS values of supported and not supported Science and Social Science papers separately, as they are similar to those in Fig. 4. Percentages of supported Science and Social Science papers in the sample were 37% and 39%, respectively. The percentage of supported Social Science papers that appeared in journals with no (zero) JIF values (17%) was much higher than that of Science papers (2%) because Social Science papers got supported more generously to increase their number (Tonta, 2017b).

We also looked at if supported papers were published in journals listed in higher JCR quartiles under their respective subject categories. It is interesting to note that more papers that appeared in journals with the lowest citation impact (Q4) were supported (28%) than those with the highest citation impact (25%) (Table 3). Almost half (48%) the supported Science papers appeared in Q1 and Q2 journals (as opposed to 36% of supported Social Science papers) (Table 4). The percentage of Science papers published in Q1 journals (26%) is almost twice that of Social Science papers (14%) (Fig. 5). The percentage of supported Social Science papers with no quartiles was the same as those with no JIFs (17%). The difference between the quartile distributions of supported and not supported Science papers was statistically significant ($X^2(4) = 39.6, p < .05, r = .01$). This may be due to the more restrictive support policy towards Science papers published in the lowest quartile of journals (Tonta, 2017b, pp. 23-24). The percentages of supported papers by quartiles suggest that the support system seems to have failed to be more selective, thereby rewarding more papers that were published in journals with lower JCR quartiles and thus lower citation impact.

[2] Not all journals in which TR-addressed papers were published had both JIF and/or AIS values listed in JCR. The correlation coefficient is based on 3,961 papers with both values. Papers that were published in journals with no JIS and/or AIS were also excluded.

The main findings of this study with regards to about 226,000 TR-addressed papers published between 2006 and 2015 are as follows: They were published in relatively low impact journals. More than half appeared in journals with AIS values well below the world average of AIS value for all journals (1.000) indexed in WoS. TR-addressed papers did not get cited very often, as half the papers received between zero (13%) and five citations within the study period. Supported and not supported papers collected comparable number of citations per paper. Supported and not supported papers were not significantly different from each other in terms of JIFs, AISs, and quartiles of journals in which they were published. The distributions of the supported and not supported Science and Social Science papers by citation impact values did not differ much, either.

Findings of the current study corroborate to some extent the findings of earlier studies of PRFSs (Auranen & Nieminen, 2010; Butler, 2003, 2004; Checchi, Malgarini, & Sarlo, 2019; Geuna & Martin, 2003; Good et al., 2015; Osuna, Cruz-Castro, & Sanz-Menéndez, 2011). We have not observed a negative correlation between JIFs, AISs, and quartiles of supported and not supported TR-addressed papers. Yet, the average number of citations per paper and JIF, AIS and quartile values were quite similar for both supported and not supported papers, indicating that the support system of TÜBİTAK has not increased the citation impact of TR-addressed papers, which confirms the findings of an earlier study (Tonta, 2017b).

We lack empirical data as to why the support system did not have any considerable effect. One reason might be that researchers have had to write papers for tenure and academic promotion anyway. Or, they may have found support through other sources (e.g., project budgets or other academic incentives). Yet another reason might be that the amount of support (based primarily on JIF values) was perhaps not attractive enough for some researchers, especially when we consider the fact that many TR-addressed papers were published in relatively low impact journals and the total amount per paper has to be divided by the number of co-authors (Tonta, 2017b).

Concluding Remarks

Findings indicate that both supported and not supported TR-addressed papers were somewhat similar in terms of average number of citations per paper. They have been published in journals with similar JIFs, AISs, and quartiles. Contrary to the expectations of the research funders, payments transferred to researchers through the support program do not seem to have played much role in improving the citation impact of TR-addressed papers. This suggests that subsidies based on bibliometric measures function poorly as incentives to increase the quantity and quality of the scholarly papers.

The support system seems to have rewarded the authors of papers who published in mediocre or low impact journals relatively more often. Despite comparatively lower "piece rates" paid for papers published in such outlets, many researchers sought financial support nonetheless. This might be an indication that subsidies may have encouraged some researchers to develop "opportunistic behavior" and act like "rent seekers" interested only in reaping the relatively modest monetary benefits of the support program without much consideration for the quality of their papers, a conjecture begging further research.

In conclusion, the support program of TÜBİTAK and similar academic incentives of the Turkish Higher Education Council should be reconsidered.

Acknowledgements

We thank Mr. M. Mirat Satoğlu of TÜBİTAK for providing data for supported papers, and Dr. Umut Al of Hacettepe University for reviewing an earlier version of this paper.

Abstract

Studying the history of research fields by analyzing publication records and topical and/or keyword searches with a full Reference Publication Year Spectroscopy (RPYS) has been introduced as a powerful tool to identify the corresponding root publications. However, for a rather new and interdisciplinary research field like Solar Energy Meteorology (SEM), this method is not feasible to get a reasonably exhaustive publication set. Therefore we apply its variant RPYS-CO to all publications co-cited with one highly important marker paper, using the CRExplorer for plotting and inspecting the spectrogram of the number of cited references. Examining its peaks and their main contributing publications, we get a list of seminal papers, which are able to adequately tell us the story of SEM up to the 1990s. Generally, we recommend this method to gain valuable insights in (new) research fields.

Introduction

Solar Energy Meteorology (SEM) studies how solar radiation can be utilized for solar energy conversion to provide heat or electricity and how the performance of these conversion processes is affected by meteorological influences. This is largely the question of its availability in time (e.g., time of day, year) and space (e.g., geographical location, angular orientation). The quality of radiation then matters when different devices are used: Concentrating devices need *direct* radiation to work whereas non-concentrating photovoltaics, i.e., solar cells, can also utilize the *diffuse* fraction of sunlight, usually scattered in the atmosphere. So, the main fields of investigations are (i) measurements and their evaluation over different time scales and (ii) modeling of radiation and its components, depending on physical (e.g., solar constant, equation of time), geometrical (e.g., position of the sun, orientation of the converter) and meteorological (e.g., cloud coverage, aerosol concentration) parameters. Both fields also involve a lot of statistical treatment.

With the availability of geostationary weather satellites, for example the European METEOSAT, methods based on satellite data have been developed in several research groups since the 1980s. One of the authors has been a member of Oldenburg University's research group on Energy Meteorology for some time, so it came naturally to investigate this field of research with bibliometric methods in order to identify seminal and landmark papers, that lead up to the state of the art at the beginning of the satellite era in SEM.

Due to its intrinsic interdisciplinarity, potential search terms tend to have multiple meanings, which leads to answer sets from title or topical searches with low precision and/or recall. Therefore, we use the bibliometric method Reference Publications Year Spectroscopy (RPYS), introduced by Marx, Bornmann, Barth, and Leydesdorff (2014), but in a variant called RPYS-CO (for co-citation), where there is no need for an exhaustive paper set covering most of the research field. In RPYS-CO, the analyzed publication set is defined by at least one marker paper. All publications co-cited with this marker paper are included in the RPYS analysis. The RPYS has successfully been applied to identify the root publications of climate change research by Marx, Haunschild, Thor, and Bornmann (2017). In that case a set of more than 200,000 papers has been used. In a subsequent approach in the same paper, Marx, et al.

(2017) refined this large set to the greenhouse effect by keeping only cited references that are co-cited with Arrhenius (1896) and were able to retrieve the results of the RPYS on the full publication set regarding the greenhouse effect, but also lesser known works of relevance. They named this RPYS variant RPYS-CO. In another very recent study, (Haunschild & Marx, 2019) compare their own results of a RPYS on density functional theory, a very frequently applied method in computational chemistry (Haunschild, Barth, & Marx, 2016), with an RPYS-CO using *one single* seminal paper with a high citation count and find a striking similarity with the results of the analysis based on a search in controlled vocabulary.

Encouraged by these results, we set out here to investigate all publications co-cited with one highly-cited marker paper, a choice discussed with and corroborated by the long term leader of the Oldenburg group: *The interrelationship and characteristic distribution of direct, diffuse and total solar radiation* (Liu & Jordan, 1960). In order to indicate the importance of this marker paper we quote its complete abstract, emphasizing in italics all those concepts and terms that proved to be prevalent in SEM for its whole history:

"Based upon the data now available, this paper presents relationships permitting the determination on a *horizontal surface* of the instantaneous intensity of *diffuse radiation* on *clear days*, the *long term average hourly and daily sums* of diffuse radiation, and the daily sums of diffuse radiation for various categories of days of *differing degrees of cloudiness*. For these determinations, it is necessary to have, either from actual measurements or estimates, a knowledge of the *total (direct plus diffuse) radiation on a horizontal surface* – its *measurement is now regularly made* at 98 localities in the United States and Canada. For localities where only an *estimate of the long term average total radiation* is available, *relation-ships* presented in this paper can be utilized to determine the *statistical distribution of the daily total radiation at these localities*." (Liu & Jordan, 1960, abstract)

Satellite-based studies often view this paper as text book knowledge. Therefore it is affected by obliteration by incorporation (Cronin & Sugimoto, 2014) and rarely cited in this area of SEM, that gained traction in the late 1980s and early 1990s. The latter are consequently a natural end date for our study of cited references, co–cited with (Liu & Jordan, 1960). The then flourishing satellite-based publications could and should be the target of further investigations using other marker papers. On the other hand, due to the recency of the research field, we do not expect decisive contributions to SEM before 1900.

There are some studies with very different time frame, focus or methodology, e.g.: Du, Li, Brown, Peng, and Shuai (2014) analysed the solar energy literature from 1992 to 2011, but with no consideration of energy meteorology topics. A bibliometric analysis on solar power research between 1991 and 2010, again after the period of our study, has been performed by Dong, Xu, Luo, Cai, and Gao (2012) using terms as, e.g., "solar radiation" in a topical search in the WoS. Their goal was to identify research trends for the twenty-first century and not to explore historical roots. In the same vein Yang, Kleissl, Gueymard, Pedro, and Coimbra (2018) tried to identify key innovations for the future of research in "solar radiation and PV power forecasting", a field mainly emerging at the turn of the millennium. They based their work on the first 1000 hits of a keyword search in Google Scholar and applied machine learning and text mining methods to full texts in order to complement conventional topical reviews.

To the best of our knowledge, the present study is one of the first using the method RPYS-CO in order to identify seminal papers for a research field – thereby complementing qualitative knowledge of experts by a quantitative evaluation of the citation counts (i.e., the reference counts within the topic related literature). Using this method we were confident to find by this method those important contributors and their papers which tell the story of the emergence of solar energy meteorology from around 1900 up to the beginning of the 1990s. So we support the suggestion of (Haunschild & Marx, 2019) that this method can help researchers to explore their field of study - in a way complementary to a usual topical or keyword-based literature search.

Method and data set

As of 8 January 2019, Liu and Jordan (1960) had 1032 citing papers in the WoS until the end of 2018. One fourth of these papers (n=257, 25%) as well as the marker paper itself have been published in a single journal, *Solar Energy.* Their four most important WoS subject categories in the data set used in this study are *Energy Fuels* (n=673, 65%), *Green Sustainable Science Technology* (n=151, 15%), *Meteorology & Atmospheric Sciences* (n=131, 13 %), and *Thermodynamics* (n=114, 11%), thereby reflecting the multiple foci of SEM.

We downloaded the bibliographic data of the 1032 papers including 36,635 cited references (CRs) from the WoS (selecting "Save to Other File Formats" and "Other Reference Software") and imported them into the CRExplorer. (The JAVA based software can be downloaded for free from http://crexplorer.net and a comprehensive handbook explaining all functions is also available.) It provides a graphical display of the number of CRs (NCR) over the reference publication years (RPY) and a tabular presentation of the NCR of all CRs. In our case there were only single occurrences of CRs before 1900. After 1995, despite a sequence of steadily increasing peaks, no specific papers of main contribution (more than a share of 10% of the NCRs in the specific RPY) could be identified. Both facts confirm our choice of the time period to be analyzed.

Much of the processing can comprehensively and reproducibly be done by using the CRExplorer scripting language: With the script in Listing 1 we `import`ed the WoS file and got 8383 unique reference variants for the reference publication years 1900 to 1995. After that `cluster`ing and `merg`ing of equivalent CR variants was done with Levenshtein threshold 0.75 and taking volume and (starting) page number into account, thereby reducing the number of CR variants by 109. Then we `remove`d all publications with only *one* citation, in order to reduce noise. In the end, we retained 1566 CRs. The results including the NCR and other indicators were `export`ed to CSV files for further inspection and plotting of the spectrogram, which can be done by using the R package BibPlots (see: https://cran.r-project.org/web/packages/BibPlots/index.html and https://tinyurl.com/y97bb54z).

Listing 1. CRExplorer script to perform RPYS on the WoS papers citing Liu and Jordan (1960)

In the spectrogram, we looked for publication years with significantly higher NCR than other years, aided by the deviation of NCR from the 5-year-median of NCR (taking into account the two preceding and the two following years). For the papers that, by applying this methodology, seemed primarily responsible for the peaks a manual merging was done, if needed.

Results

Figure 1 shows the spectrogram of the RPYS-CO for the marker paper (Liu & Jordan, 1960) in terms of the NCR and their 5-year-median deviation for the whole analyzed time period, and Table 1 lists all publications, contributing substantially to the peaks of NCR and identified as relevant.

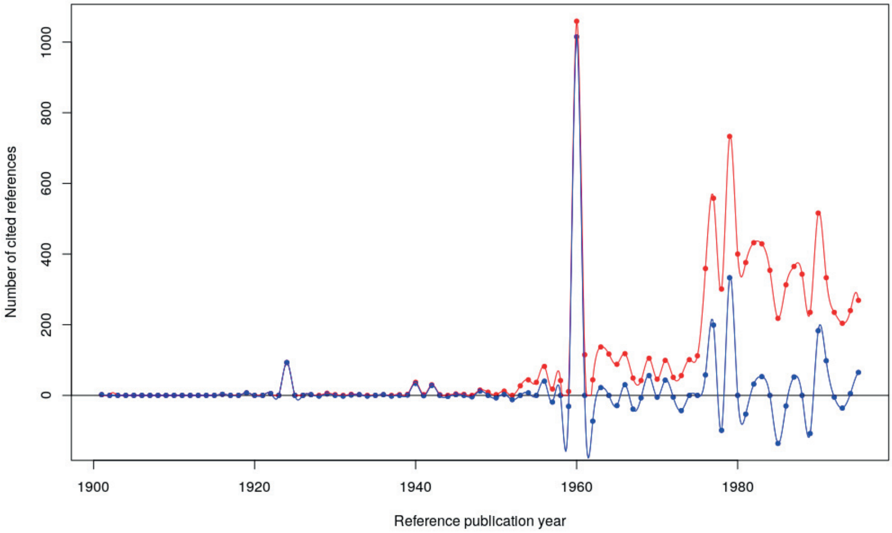

Figure 1. Overall RPYS-CO graph for Liu and Jordan (1960) with NCR (red line) and 5-year-median deviation (blue line)

Table 1. RPYS-CO for Liu and Jordan (1960): important CRs from 1900 to 1995 with number of citations NCR and indicating, if manually merged during inspection of spectrogram

The overall RPYS-CO picture can easily be divided by the maximum NCR per RPY into two periods with regard to the reference publication years, which we are going to discuss separately: the first one from 1915 leading to, but excluding, 1960, the publication year of the marker paper, containing peaks with at most NCR=100; the second one from 1960 to 1995, with peaks between NCR=100 and NCR=900 (apart from the marker paper itself).

Time Period 1: 1915 to 1959

Figure 2 shows the RPYS-CO spectrogram for the marker paper (Liu & Jordan, 1960) for the relevant time period before it was published.

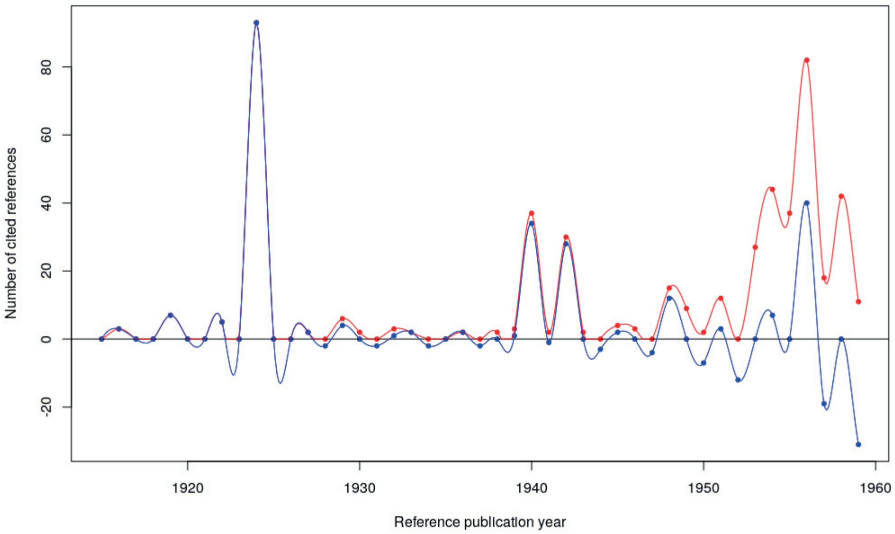

Figure 2. RPYS-CO graph for Liu and Jordan (1960) and period 1 (1915 – 1959) with NCR (red line) and 5-year-median deviation (blue line).

In this time period, we were able to identify 9 peaks with *relevant* papers for the following RPYs: 1919, 1922, 1924, 1929, 1940, 1942, 1945/46, 1948, and 1953-58. Because of the generally low NCR values in this time period, we did not want to lose reference variants of possibly relevant papers and therefore additionally looked at the CRs *before* the removal of only once referenced papers. But this did not reveal new relevant papers, instead it only confirmed the results from the reduced set.

Now we can follow the path of SEM by looking at the peak papers and drawing partially from explanations given in the citing papers. In this first period, two independent streams of research flew together: *meteorology* and *engineering*.

Meteorologists tried to develop a climatology of irradiance, emphasizing daily mean values, with no or little application to solar energy in mind. Solar irradiance varies deterministically with the sun's position on the sky dome and irregularly with changing cloudiness. The relation of the latter with sunshine has initially been measured by Kimball (CR1) and later subjected to statistical analysis by Angström (CR2, CR4, and CR5), leading to a linear relation between the duration of bright sunshine and average solar energy available on a horizontal surface at ground level, the so-called *Angström equation*. This has been generalized to the *Angström–Prescott* (CR6) *equation* by introducing a *daily clearness index*, quantifying all stochastic meteorological influences, as a measure of the atmospheric transparency (Paulescu et al., 2016). Linke (CR3) in 1922 published his *turbidity factor* for the attenuation of the sun's radiation by water vapor and aerosols in the atmosphere. Later Black, Bonython & Prescott (CR12) gave a linear regression relation between solar radiation and the duration of sunshine based on monthly values (Munkhammar & Widen, 2016) and Glover & McCulloch (CR15) improved this by including latitude effects.

Two *engineers*, Hottel & Woertz (CR7), came up with the first serious study on solar energy in 1942: the fundamental relationships given in their classic paper have since then been used for decades to model solar collectors. Hottel & Whillier (CR13) evaluated them concerning the flat-plate solar collector performance (Stanciu, Stanciu, & Paraschiv, 2016) and formulated the *Hottel-Whillier-Bliss equation* on its heat flow and available heat balance, based on considerations of the thermal usability of solar irradiation, coming from Whillier's PhD thesis (CR11) under Hottel's supervision at MIT. This latter work concerned also the relation between radiation on different time scales, showing a close interdependence of the frequency distributions of the so-called clearness index on a monthly, daily, and hourly basis (Vijayakumar, Kummert, Klein, & Beckman, 2005). Because information on sunshine duration was no longer sufficient, he later proceeded to "The determination of hourly values of total solar radiation from daily summations" (CR14) by statistical means, a subject still of great importance for SEM, where still an ever more time-resolved knowledge of solar irradiance is needed.

The *modeling* of solar irradiance components through parameterization of atmospheric phenomena is an equally important area of work in SEM. It was begun in the 1940s by Haurwitz (CR8-CR10), focusing on cloudiness, cloud density, and cloud type (Chowdhury, 1990). (We do not include a publication from the 1948 peak by Penman with NCR=8, i.e. more than CR10, because it is only concerned with evaporation by solar radiation.)

Time Period 2: 1960 to 1995

Figure 3 shows the RPYS-CO spectrogram for the marker paper (Liu & Jordan, 1960) after its publication year.

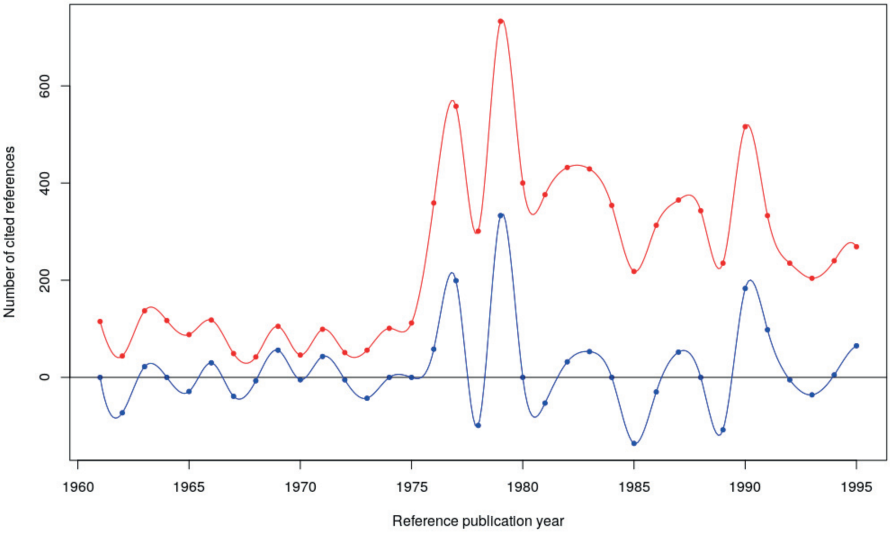

Figure 3. RPYS-CO graph for (Liu & Jordan, 1960) and period 2 (1960 – 1995) with NCR (red line) and 5-year-median deviation (blue line). For better presentation, the RPY 1960 is excluded.

Another 10 peaks could be identified from Figure 3 for the following RPYs in the second time period: 1960, 1963/64, 1966, 1969, 1971, 1976/77, 1979/80, 1981-83, 1986-88, 1990/91.

The first two peaks are mainly caused by *engineers*: After the marker paper itself (CR16) the same authors gave generalized curves to predict the "Long-Term Average Performance of Flat-Plate Solar-Energy Collectors", making use of Hottel's and Whillier's methods (CR13) and building upon the knowledge of two parameters only: i) the monthly-average daily total radiation on a horizontal surface and ii) the monthly average day-time ambient temperature (CR17). In 1961, J. K. Page presented "The estimation of monthly mean values of daily total short-wave radiation on vertical and inclined surfaces from sunshine records for latitudes 40N-40S" **(**CR19**)** on a "UN Conference on New Sources of Energy" in Rome but the conference proceeding was published in 1964. Much later, he advised advanced publicly funded projects like HELIOSAT-3 (Mueller et al., 2004).

The *meteorologist* F. Kasten (CR22) developed turbidity models as one essential ingredient for radiation model calculations and also functioned as an advisor in later solar energy projects.

Attempts to check and confirm the *diffuse-to-total radiation correlation* by Liu and Jordan (1960) against *measurements* have been undertaken for several locations in the world: Southern Israel by Stanhill (CR20), New Delhi by Choudhury (CR18), and Canada by Ruth and Chant (CR27) and Tuller (CR29).

Cooper (CR23) and Spencer (CR25) are the only representatives in Table 1 of those researchers concerned with *solar geometry*, i.e. sun-earth angle values over time – which is essential for all modeling of radiation. In this respect, our method could only capture these first works, but not later standard works like Michalsky (1988).

Robinson's "Solar Radiation" (CR21) was a meteorological standard publication, but not that much focused as Kondratyev's monograph "Radiation in the Atmosphere" (CR24), whose influence lasted until Iqbal's standard work "Introduction to Solar Radiation" (CR41) from 1983.

In the 1970s and early 80s, one focus of research literature was on *time-resolved diffuse radiation models from the scale of months down to hours*, mostly from the viewpoint of *engineering* like Duffie & Beckman's volumes "Solar Energy Thermal Processes" in 1974 (CR26) and "Solar engineering of thermal processes" in two editions in 1980 (CR37) and 1991 (CR49), but also Hottel (CR28), Orgill & Hollands (CR31), Klein (CR32), and Erbs, Klein & Duffie (CR40). Only Hay (CR30) and Iqbal (CR38) represent *geography* resp. *meteorology*. *Empirical radiation modeling*, in particular with respect to tilted surfaces (e.g., of solar panels), was done by Hay (CR36) and *meteorologists* as Temps & Coulson (CR33) and Klucher (CR35).

At the end of the 1970s, the focus switched also to *stochastic modeling*, outstandingly covered by Collares-Pereira & Rabl (CR34) with their time series analysis and production of the *first synthetic time series*, that were widely used in the community. In the same vein, Bendt presented his "frequency distribution of daily insolation values" (CR39). The time-scale was later even narrowed down to *minute data* by Suehrcke & McCormick (CR44), and Graham, Hollands & Unny (CR45) were able to *simulate daily values* of the clearness index from monthly mean values by using probability distribution functions.

In 1987, Skartveith & Olseth (CR42) presented a *diffuse fraction model*, that became essential part of later works, e.g. in HELIOSAT (Dürr & Zelenka, 2009). CR43, i.e., Perez, Seals, Ineichen, Stewart, and Menicucci (1987), also focused on the diffuse part of total irradiance and accomplished a major improvement in its error-prone computation, in order to "estimate short time step (hourly or less) irradiance on tilted planes" (Perez, et al., 1987), which has received high recognition in the community. (See *Discussion & Conclusion* for considerations to use CR43 as a second marker paper.)

Duffie & Beckman, together with their coauthor Reindl, were mainly responsible for the last high peak, taken into account in our RPYS-CO analysis, in 1990: they *evaluated statistical models for hourly radiation on the tilted surface* (CR47) and could significantly *improve on the time resolution of statistical diffuse radiation models* in CR46, whose abstract we now quote (with our emphases in italics): "The influence of climatic and geometric variables on the *hourly diffuse fraction* has been studied, based on a data set with *22,000 hourly* *measurements* from five European and North American locations. The goal is to determine if other predictor variables, in addition to the clearness index, *will significantly reduce the standard error* of *Liu- and Jordan-type correlations* (…). Stepwise regression is used to *reduce a set of 28 potential predictor variables* down to *four significant predictors: the clearness index, solar altitude, ambient temperature, and relative humidity***.”** (Reindl, Beckman, & Duffie, 1990, abstract)

We can in a sense close the circle to our marker paper after exactly 30 years by mentioning CR48, i.e., Perez, Ineichen, Seals, Michalsky, and Stewart (1990), as a successful attempt to *apply diffuse fraction models* to questions of *daylighting in buildings*, transferring irradiance to illumination, and again connecting the fields of *meteorology & radiation* to *energy & engineering*, the two-fold focus of SEM.

Discussion & Conclusion

We studied the early history of SEM by applying RPYS-CO to one highly cited and relevant marker paper (Liu & Jordan, 1960), matching the recommendation of a long-term expert, inspected RPYs with peak citation numbers in the corresponding graph and table calculated by the CRExplorer and were able to thereby identify many important papers before and after the marker paper. They give an adequate view of most of the essential contributing streams of research in SEM, as, e.g., measuring, empirical and statistical modeling of direct and diffuse radiation on the horizontal and the tilted plane on time scales from years to minutes. The topics *solar geometry, radiative transfer* calculations through the atmosphere, and *spectrally resolved* treatment of sun light can be identified as underrepresented in our RPYS-CO results. But the latter two in particular gained interest only in later years and should be studied with other marker papers.

It could also be argued that an RPYS-CO on one or few marker papers only produces a bias by favoring a limited number of research groups, maybe even enforced by the effect of self-citations. But in the given case the marker paper is obviously so well chosen as to unearth a diverse set of methodologies and approaches in the world-wide SEM community, coming from the two main domains *meteorology* and *engineering* and covering *measurement*, *modeling* and *evaluation*. (This could be different when we are going to study the satellite based methods, where European and US research groups take slightly different approaches.) Moreover, self-citations of the admittedly repeatedly occurring (co-)authors among the peak papers play no role in our study because of their sporadic appearance.

CR43 (Perez, et al., 1987) had been suggested as a second marker paper by the expert, but as it turned out, the RPYS-CO on both papers only confirms the results for Liu and Jordan (1960) alone, as Figure 4 shows. Some NCR peaks get sharpened, but there are no new ones found. Furthermore, a RPYS-CO analysis on CR43 alone would reveal less peak papers than the RPYS-CO as performed here. An even stronger confirmation results from another RPYS-CO conducted for the two top most cited papers in our list of CRs, i.e., CR34 (Collares-Pereira & Rabl, 1979) with 238 citations and CR40 (Erbs, Klein, & Duffie, 1982) with 208 citations: *all* peaks and peak papers get reproduced, except from one in 1948 (CR10)!

Moreover, none of the potential candidates in our list of CRs got nearly as many citations as Liu and Jordan (1960) in the whole Web of Science. These facts corroborate the careful choice of the marker paper and the stability of the method’s outcomes.

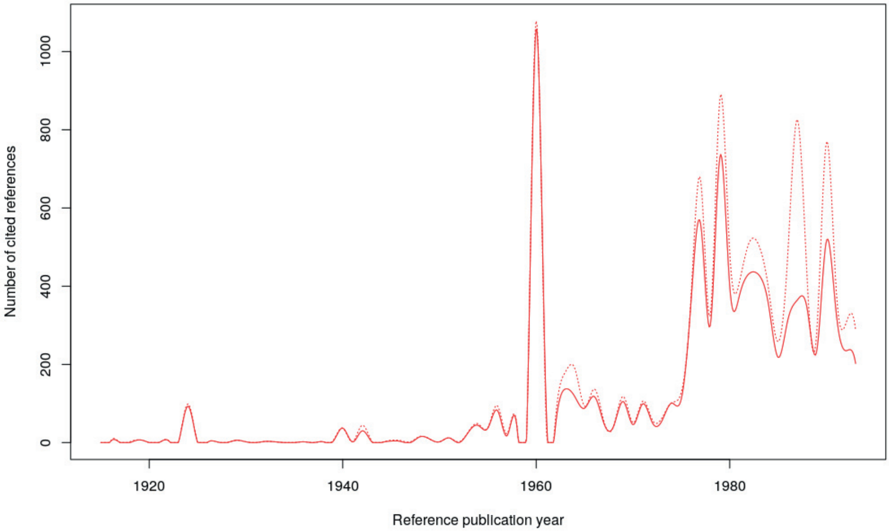

Figure 4. Comparison of the RPYS-CO for the marker paper Liu and Jordan (1960) (solid line) and the RPYS-CO for the marker paper plus the potential second marker paper Perez, et al. (1987) (dotted line).

In total, the outcome of our study meets our expectations: All relevant historical roots of SEM research were disclosed by our RPYS-CO analysis. Therefore, we recommend RPYS-CO for similar investigations by researchers to get more insight in the development of their field of work or even as a tool for studies in the history of science.

Acknowledgments

We want to thank Detlev Heinemann for very useful discussions on the "early story of Solar Energy Meteorology" and comments regarding an earlier version of this manuscript. We also thank Lutz Bornmann for helpful discussions.

Abstract

This study construct a systematic approach to explore how the advantages of the network position formed by the litigation of the dental firms with what patent portfolio they adopted based on the Actor-network Theory (ANT). The dataset is from 1995 to 2018 the 592 litigation dental patent, 640 litigation case and 240 plaintiffs and 548 defendants that formed a 550 firm matrix analyzed in the UCINET. The systematic approach include six approach: (1) calculate the social network variables-degree centrality and structure holes; (2)cluster analysis; (3)validation of cluster solution and cluster interpretation; (4)patent portfolio analysis. The cluster analysis show 6 cluster: Key player 1, Key player 2, Patent troll, Active Attacker, Bystander and Victim, to explore the position of each firm in the litigation network. The result show that key player1 and 2 use multiple patent portfolio to get competitive advantage. 3 Patent troll use only one patent or one patent portfolio to sue defendants. 23 Active Attacker firms has less patent portfolio than key players. The results will provide a broader theoretical perspective for the governance of network relations between organizations through litigation, and also provide practical advice for managers to understand the development of litigation networks and patent portfolio.

Introduction

In technology-driven industry, the IP war had become an important means for business competition. The patent right was that the country gave the right to create a legal monopoly market for the inventor. It was common for competitors to use patent litigation as a means of commercial competition. In the practice case of US patent litigation, litigation compensation may be as high as several billion dollars or quit the market due to the loss of the lawsuit. Besides, the Patent Troll had become increasingly popular in the United States in recent years and also use patent infringement lawsuits to get extra profit.

Therefore, how to develop patent portfolios strategy in response to patent litigation should be an important issue that business operators must consider in advance. For the purpose, the study took the medical equipment industry as an example to explore what the patent portfolio strategy that adopted by the manufacturers in the network position advantage formed on the entire litigation network was. In a patent litigation reconciliation funds may not be the final purpose, to file an infringement lawsuit may be a strategy to threaten competitors as a containment to stop them to enter market. From the patent strategy practices the firms would form a defensive patent pool as a countermeasure against patent litigation. It could select a number of patents with important strategic value in a specific technology field through jointly purchased or developed by different in order to react against a specific patentee’s monopoly. For example, Google spent $12.5 billion to acquiring Motorola Mobility that owned 17,000 patents, and then licensed the aggressive and powerful patents to Android smartphone makers with low prices to fight back to Apple.

Thus, in a fast and highly complex business environment, it is an important theoretical and practical basis for managers to understand what competitors will initiate a patent lawsuit, how they have sued with what kind of patent portfolio and how the defendants have reacted against the lawsuit. From the social interaction perspective, it is a key issue to analyze the relationship development of the organization in the network, to demonstrate the structure of the network and the position of firms and their competitors based on the governance mechanism and the arrangement of interests of the organization through cooperation, litigation or safeguard strategies (Jones et al., 1997).

Many studies have analyzed network structure to explore how the performance generated through economic transactions or resource exchanges among organizations (Jones, Hesterly, & Borgatti, 1997; Borgatti & Halgin, 2011; Bizzi & Langley, 2012). However, many studies have clarified structure of the network or position of actors by showing the role, ties or position of actors. This kind of study is useful to explain or understand the relationship of companies and what benefit they got through. It oversimplifies the overall development of the network, and it is difficult to meticulously describe the details of how the interactions between organizations, what governance mechanism actor adopted to react, cooperate or attack other actors and what the development of inter-organizational network relationships.

Accordingly, this study focus on both human (firms) and the non-human actor (patent portfolio), emphasizing the evolution between firms and their patent portfolio. This is the basic spirit of Actor-network Theory (ANT), which emphasizes action, evolution, and context. This study explore the development of litigation relationship network, discovers the relationship among plaintiffs and defendants and how plaintiffs used patent portfolio to obtain their network advantage or how defendants develop patent portfolios in response to patent litigation.

This paper takes the medical device industry as an example and construct a systematic approach to explore the advantages of the network position formed by the litigation of the dental firms and what patent portfolio they adopted in the entire litigation network based on the ANT theory. The results will provide a broader theoretical perspective for the governance of network relations between organizations through litigation, and also provide practical advice for managers to understand the development of litigation networks and patent portfolio.

Litigation Network and Social Network Indicators

Social network refers to a group of specific social relationships that are connected by actors. Actors and relationships are the basic elements of network analysis. Any actors are nodes in network could be an individual, an organization, a patent or a technology depends on research purpose. The connection (tie) between nodes expresses the relationship and flow between actors. In the social network analysis, many research have provide various network indicators to measure or explain various phenomena. In this study we adopted two network indicators- degree centrality and structure how to explain the structure of patent litigation network.

Centrality

Each actor has its positon in the social network structure. The structural position affects the actor's ability to control resources. When an actor is at the center of the network, it can control related resources and obtain more benefits (Ibrra, 1993). The centrality of social networks is used to measure the influence of actors in the network, and Freeman (1979) has proposed three measures, namely degree centrality, closeness centrality and betweenness centrality.

- **Degree centrality**

Degree centrality is to observe the connection relationship between a node and surrounding nodes. The more nodes a node is connected to, the more it has the informal power and influence associated with more actors in the network. Wassermann and Faust (1994) definite that the core member with more degree centrality must be the most active has the most ties to other actors in the network. Degree centrality only considers the direct link of the actor

- **Closeness centrality**

Since the degree centrality only considers the direct link of the actor, however, an actor may be connected to many nodes that may not have much connection with other ones in the entire network. Closeness centrality emphasizes the distance between actors and others, focusing on the distance between actors (Hanneman & Riddle, 2013). The connection among all points of the overall network will be measure, which can be used to determine the proximity of an actor to others. The shorter the distance from others, the higher the proximity to the center, indicating that they can obtain information faster.

- **Betweenness centrality**

Betweenness centrality treats actors as being between other peers of the network and is considered a dominant position. The more actor rely on me to connect with others, the more power I have. If two actors have more than one path to form connection, but I am not on these paths, I lose some power (Hanneman & Riddle, 2013). That is, the interaction of any two actors of the network relationship must be linked through a key point (Borgatti, Carley, & Krackhardt, 2006).

In this study, there is no broker between plaintiffs and the defendant and the distance between the nodes is not meaningful. Therefore, this study only analyzes the degree centrality. The higher the degree centrality, the more nodes are connected to the node and associated with more actors, indicating that the node is the most active in the network, and also has a strong influence.

Structure Hole

Most social structures tend to be characterized by strong or weak connections. The structure hole theory relies on a fundamental idea that the homogeneity or redundancy of information, new ideas, and behavior is generally higher within any group of people as compared to that in between two groups of people (Burt, 1993). An individual who acts as a mediator between two or more closely connected groups of people could gain important comparative advantages. Burt (1997) investigated the bankers in large financial organizations found that there is a negative correlation between network restrictions and dividends. Besides, the results also shown that managers who cross the structural hole under the same conditions will receive higher salaries (Burt, Hogarth & Michaud, 2000). Geletkanycz and Hambrick (1997) believe that when senior managers master the relationship between cross business boundaries or subcompanies are more likely to achieve good performance (Geletkanycz & Hambrick, l997).

Also, we think there has the same effect in the patent litigation network. If we compare two nodes (plantiff) has the same out-dergree that sued three defendants, node A is more likely to get complex technology information with different types of patent portfolio than node B and control the litigation network. This is so because nodes connected to B are also highly connected between each other. Other nodes has ability to sue node B and each other overlapped in the same technology fields, so connections involving node B are said to be redundant. On contrary, the position of node A makes it serve as a bridge between three different clusters that firms have different type technology portfolio. As Parchomovskt & Wagner (2005) think that patent portfolio with scale effect and diversify effect could create more value and get competitive advantage through increasing litigation potential and opportunity of cross-license. Thus, node A is likely to control non-redundant technology information from other competitors. Structural holes is used to measure non-redundant contacts and provide network benefits to node A.

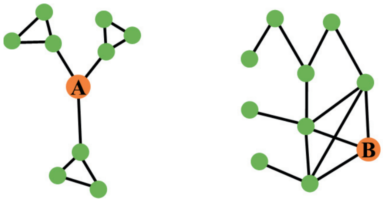

Figure 1. Two types of litigation network structure

Patent Portfolio Strategy

The concept of patent portfolio (Patent Portfolio) was first proposed by Brockhoff in 1991. Parchomovskt & Wagner (2005) think that a patent portfolio is a collection of all relevant patents for a particular technology field that can construct a patent pool to defense, increasing technology licensing opportunities, and increasing barriers to entry. Wagner (2005) proposed the concept of patent portfolio, to assume that a new patent is added to a patent portfolio, and its expected marginal benefit will be greater than the marginal cost of obtaining the patent and to achieve synergistic effect.

Parchomovskt & Wagner (2005) believes that the true value of patents is not the focus on individual patents, but the advantages of scale and technical diversity of patent portfolio of patents. Parchomovskt & Wagner (2005) think that the value created by the patent portfolio includes (1) Economic value: establishing a competitive position through patent infringement agreements and patent cross-licensing by using patent portfolio. (2) Scale effect: Scale effect is also called scale economy. The overall value of the company's patents is also the embodiment of economies of scale in the patent portfolio. (3) Monopoly effect: Monopoly effect refers to that enterprises have a strong patent portfolio strategy in a certain technology field, and form a certain “patent barrier” to protect corporate R&D activities and their freedom operation. (4) Risk minimization: Since the patent portfolio is a collection of multiple interrelated patents, it is possible to avoid costly patent litigation caused by patent infringement and to maximize the benefits under the principle of minimizing risk based on the patent portfolio.

Methodology

Data Retrieval

In this study, we collected litigation patents belong to the IPC of dental medical device introduced in table 1 from WIPS Infringement Search and Patentability Search database (https://www.wipsglobal.com/service/mai/main.wips). This study used the keywords "tooth" or "oral cavity" to search definition of IPC from the TIPO's IPC search system and manually screened the IPC definition. We deleted the 90 IPCs that were not related to dentistry from 159 IPC categories. Finally, the technology defintion of 14 IPC classes as shown in Table 1 is dental device technology.

Table 1. Major sub-class of IPC in dental medical device patent.

IPC	*Definition*
A46B 9/04	Position or arrangement of bristles in relation to surface of the brush body for toothbrushes, e.g. inclined, in rows, in groups
A61B 1/24	For the mouth, i.e. stomatoscopes, e.g. with tongue depressors; Instruments for opening or keeping open the mouth
A61B 1/247	With means for viewing areas outside the direct line of sight, e.g. dentists' mirrors
A61B 1/253	With means for preventing fogging to viewing areas outside the direct line of sight, e.g. dentists' mirrors
A61B 6/14	Apparatus for radiation diagnosis applications or adaptations for dentistry, e.g. combined with radiation therapy equipment
A61B 17/24	For use in the oral cavity, larynx, bronchial passages or nose; Tongue scrapers
A61C	Dentistry; apparatus or methods for oral or dental hygiene
A61G 15/00	Operating chairs; Dental chairs; Accessories specially adapted therefor, e.g. work stands
A61H 13/00	Gum massage
A61J 17/02	Teething rings
A61K 6/00	Preparations for dentistry
A61Q 11/00	Preparations for care of the teeth, of the oral cavity or of dentures, e.g. dentifrices or toothpastes; Mouth rinses
F03B 13/04	Adaptations of machines or engines for use in dentistry; Combinations of machines or engines with driving or driven apparatus; Power stations or aggregates
F21W 131/202	Lighting for dentistry medical use

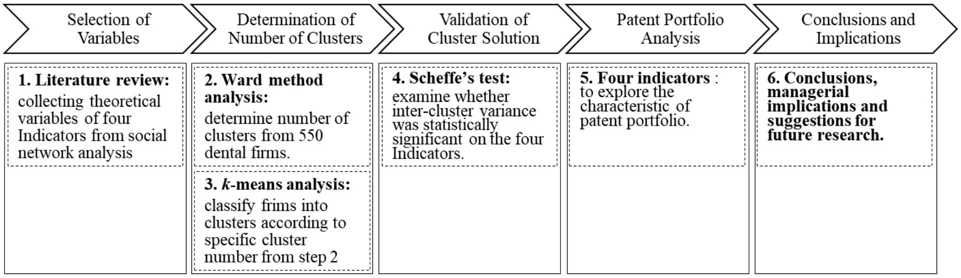
Note: TIPO's IPC search system, from https://www.tipo.gov.tw/sp.asp?xdurl=mp/lpipcFull.asp&ctNode=7231&mp=1.

From WIPS Infringement database we gathered litigation dental patents by using 14 IPC classes. Finally, from 1995 to 2018 the 592 litigation dental patent, 640 litigation case and 240 plaintiffs and 548 defendants that formed a 550 firms matrix analysed in the UCINET.
Besides, we collected detail information of the litigation patent from US patent database in the Patentability database of WIPS that will used in the patent portfolio analysis.

Systematic Analysis procedure

This study will construct a systematic analysis procedure to recognize the position of companies in a litigation network. In the step 1, we establish a data set for social network analysis. First, we collect patent litigation data in the US dental industry and to form an adjacency matrix based on plaintiff and defendant relation. Then, we compute the value of degree centrality and structure hole of each firm in the litigation network to understand the position of each firms.
In the step 2,3 we use degree centrality and structure hole of each firms in cluster analysis. In this study we adopt the two-stage cluster analysis that we first decide the proper number of clusters based on the Ward method and classify companies into clusters based on K-means clustering according to proper number from the Ward method. And then, we use MANOVA to test the significance of clusters (positions) to validate the cluster solution and named the cluster based on the network variables.
In the step 5, we use four indicators to analysis patent portfolio of each major plaintiff. The four indicators include total patent counts, what technology types the patent portfolio has been used to

sue competitor, litigation case and defendant. The framework of this study is shown in Figure 2. Finally we discuss the conclusions and managerial implications.



Selection of Variables
Determination of Number of Clusters
Validation of Cluster Solution
Patent Portfolio Analysis
Conclusions and Implications
1. Literature review: collecting theoretical variables of four Indicators from social network analysis
2. Ward method analysis: determine number of clusters from 550 dental firms.
3. k-means analysis: classify frims into clusters according to specific cluster number from step 2
4. Scheffe's test: examine whether inter-cluster variance was statistically significant on the four Indicators.
5. Four indicators : to explore the characteristic of patent portfolio.
6. Conclusions, managerial implications and suggestions for future research.

Figure 2. Research model and systematic analysis procedure.

- **Network Indicators**

Visualizing the relationship among companies in the patent infringement lawsuits network and generating network indicators. In this study we used two indexes to evaluate patent litigation network - degree centrality and structure hole. Degree centrality means that how many competitors a firm has sued or been sued. A firms with high degree centrality no matter what that firm have more ties to reach and it is the key player in the dental industry. The firms with high structure hole occupy the network structural positions that act as a source for larger volumes of information exchange and other transactions involving other resources.

➢ **Degree Centrality (in-degree centrality and out-degree centrality)**

Degree centrality can distinguish between the in-degrees and out-degrees of nodes in directed networks by measuring in-degree and out-degree centrality, respectively (Knoke and Burt 1983). In the directional patent networks, a tie has a start node and an end node. Degree centrality is used to measure the size of the actor's control range in the network. The in-degree centrality ($C_{D,in}$(ni)) and out-degree centrality ($C_{D,out}$(ni)) of a given node are formally defined as

$$C_{\mathrm{D},in}(n_i) = \sum_{j=1}^{k} r_{ij,in} \ ; C_{\mathrm{D},out}(n_i) = \sum_{j=1}^{k} r_{ij,out}$$

where $r_{ij,in}$ and $r_{ij,out}$ denote sued and been sued connections of node i, respectively, and node k indicates the network size. The in-degree of a node is defendant. The out-degree of a node is plaintill. Comparing in-degree and out-degree measures of a given node can reveal what positional relationship among different types of firms with what kind of patent portfolio in the patent litigation network.

➢ **Structural holes (Effective size, Constrain)**

Burt (1993) studied the structure of interpersonal networks, and analyzed what kind of network structure can bring to the network of actors more benefits or rewards. The so-called "structural hole" is a gap between non-redundant contacts. Structural holes were used to represent the competitive advantage for a node in which linkages spanning different. The concepts of redundancy is generally measured by the effective size of egocentric network of each node.

Redundancy can be calculated as average degree of ego's alters that not count the number of ties connected to ego node. So the effective size of an ego network is just the whole network scale minus the redundancy.
Calculate the degree of constraint of a node that is connected to another node:

$$C_{ij} = \left(P_{ij} + \sum_{q} P_{iq} P_{qj} \right)^{2}$$

Equation for the Burt constraint value of node i:

$$C_i = \sum_{j} C_{ij}$$

The definition of effective size is the ratio of the effective size divided by ni indicates efficiency on a scale from zero (highly redundant links and low efficiency) to one (no redundant links in the network).

Result

The Interpretation of Cluster in the US Dental Medical Device Industry.

We then use the Ward method to identify the number of clusters, which shows that when the number of groups is reduced from six to five, the agglomeration coefficient suddenly rises sharply (from 341.92 to 385.87). The agglomeration coefficient represents the square Euclidean distance between the two clusters joined. As such, small coefficients indicate that fairly homogeneous clusters are joined, whereas larger values indicate that dissimilar clusters are joined. Therefore, the most suitable number of groups is defined as six.

After deciding on the number of groups, we used k-means cluster analysis to divide the 550 firms into six clusters. Scheffe's multivariate comparison was used to identify the differences among groups, which shows that each of the six clustering variables is significant at $p<0.05$ respectively. Table 2 records the average scores and the results of the Scheffe's multivariate comparison of the four network indicators in the six groups. The interpretation of clusters is described below.

- **Cluster 1: Key player 1**

Statistically, cluster 1 (n = 1) reported the strongest emphasis on the entire network indicators among the six clusters. Key player 1 (Ivoclar Vivadent) has sued 29 defendant with out-degree is 29 and in-degree is zero. No companies sued Ivoclar Vivadent.

- **Cluster 2: Key player 2**

Cluster 2 (n=1) has second highest scores for network indicators. Key player 2 (Dentsply International) also high out-degree (the value is 22), but the firms has high in-degree (the value is 23). We found that three patent troll all sued Dentsply International

- **Cluster 3: Patent troll**

In cluster 3 (n=3), the score of network indicators is similar to cluster 4. But, in the cluster 3 the 3 firms are patent troll. The Patent Troll referred to a patent management company that acquired patents from others but did not engage in research and development, regarded the patents it owned as a weapon to initiate litigation, and used compensation or reconciliation funds as the main source of revenue. So we found that the in-degree of the 3 firms is only 0.667.

- **Cluster 4: Active attacker**

Firms in cluster 4 (n=4) display the similar scores in most variables when compared to the third clusters. The four firms are dental companies has higher out-degree (the value is 10.5) and in-degree is 1.5 mean that some firms have sued the four companies.

- **Cluster 5: Bystander**

In cluster 5 (n = 23), the 23 have average 1.29 patent litigation cases (the out-degree is 1.29) but have been sued by 6.2 litigation cases (the in-degree is 6.29). The 23 firms have less experience or ability to initial a patent lawsuit but the defendants that key player and patent troll have sued. We could say that firms in this cluster have marginal patent litigation ability. Therefore, cluster 5 is named the "Bystander" pattern.

- **Cluster 6 : Victim**

In cluster 6 (n = 517), the means of the four network indicators are all lower than the other clusters. Besides, the out-degree of 517 firms has lower than one and the in-degree is also lower than one. Therefore, cluster 6 is named the "victim" pattern.

Table 2. The cluster naming and result of MANOVA.

Position of Network	*N*	*EffiC*	*CON*	*OutD*	*InD*	*Company Name*
Key player 1	1	1.000	.070	29.000	.000	Ivoclar Vivadent
Key player 2	1	.991	.055	22.000	23.000	Dentsply International
Patent troll	3	.984	.115	12.667	0.667	511 Innovations, DE Partners Golden Rule, Randall s Asher
Active Attacker	4	.972	.156	10.500	1.500	3M Innovative Properties, 3M Company, CAO Group, Ultradent Prod
Bystander	23	.991	.293	1.290	6.290	American dental, Anatomage, Blue Sky Bio, Dentsply IH, Dentsply Sirona, Discus Dental, Hu-Friedy Mfg, Kerrrporation, Mylan Pharmaceuticals, Nobel Biocare Service, Nobel Biocare USA, OnDem and 3D Technology, Ormcorp, Procter & Gamblempany, Ranir, Shock Doctor, Sirona Dental Systems, TP Orthodontics, Technique D`Usinage Sinlab, The Ohio Willow Woodmpany, The Procter & Gamblempany, US Dental Depot, Zimmer Holdings
Victim	517	.996	.835	.890	.910	--

Visulization the Structure and Position of Firms in the Litigation Network.

We visulizated he patent-infringement lawsuits graph for 550 dental companies involving in the 640 patent litigation cases from 1995 to 2018. A node represents a company and an edge from node X to node Y represents the lawsuit relationships from X to Y.

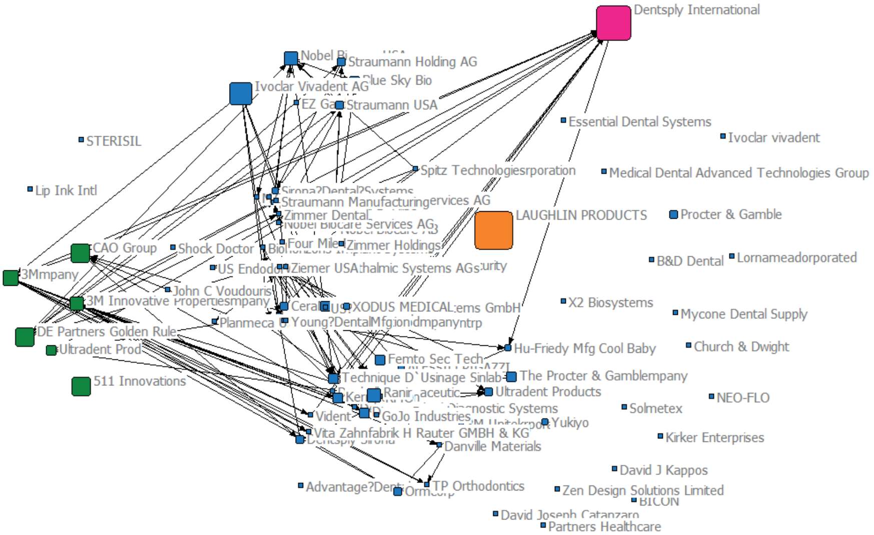


Figure 3. Position of companies in litigation related network in US dental industry.

The Patent Portfolio of major firms in the litigation network

We used four indicators (patent counts, number of patent portfolio, number of litigation cases and number of defendants) to analyze the patent portfolio of 8 major firms the litigation network. The characteristic of the patent portfolio of major firms in the litigation network shown in table 3.

Table 3. The characteristic of the patent portfolio of major firms in the litigation network.

No.	*Firms*	*No of Patent*	*No of patent portfolio*	*No of Litigation Case*	*No of Defendant*
1	Ivoclar Vivadent AG	13	5	8	27
2	Dentsply Internation	17	7	24	26
3	3M Innovative Properties	13	11	12	5
4	511 Innovations	8	1	6	23
5	DE Partners Golden Rule	1	1	12	18
6	Randall s. Asher	1	1	8	9
7	CAO	29	3	18	27
8	Ultradent Production	19	3	11	14

Conclusion and Suggestion

This study construct a systematic approach to explore how the advantages of the network position formed by the litigation of the dental firms with what patent portfolio they adopted in the entire litigation network based on the Actor-network Theory (ANT).

The cluster analysis show 6 cluster: Key player 1, Key player 2, Patent troll, Active Attacker, Bystander and Victim, to explore the position of each firm in the litigation network. Then we demonstrate the Patent Portfolio of major firms in the litigation network. The result show that key player1 and 2 use multiple patent portfolio to get competitive advantage. 3 Patent troll firms use only one patent or one patent portfolio to sue defendants. 23 Active Attacker firms has less patent portfolio than key players. The results will provide a broader theoretical perspective for the governance of network relations between organizations through litigation, and also provide practical advice for managers to understand the development of litigation networks and patent portfolio.

The IP war between technology-driven firms is likely to become more and more fierce. In the future business environment, firms should pay more attention in the management of intellectual property rights and monitor the patent litigation. Firms should upgrade their previous defensive orientation in the patent portfolio development into strategical litigation and attack competitors by using patent portfolio. Besides, it is necessary to re-examine the planning of litigation strategies in order to avoid becoming a defendant sued by patent troll.

Abstract

Information has a clear effect on the choices people make. As a vital source of information on the Web, critical inaccuracies or biases on Wikipedia may have major negative impact even when accidental, but even more so in the form of systematic bias through organized manipulation. We propose to study the latter in a case study of articles on Traditional Chinese Medicine (TCM), an area that has been identified as affected in the English language Wikipedia. We will classify Wikipedia contributors to TCM articles by their editing, referencing, and collaborating behaviours, applying two bibliometric methods: co-authorship analysis and author bibliographic coupling analysis. We will identify editor groups that appear as dense clusters in all three classifications, and test if they show characteristics previously identified as indicative of persistently biased editing. We will verify if these tightly knit groups of editors have worked together to systematically bias articles on TCM.

Introduction

Information clearly affects the choices people make, such as shifting their voting patterns (DellaVigna and Kaplan, 2007) or affecting their medical outcomes (Yom-Tov and Boyd, 2014). As a vital source of information on the Web, any critical inaccuracy (e.g., in medical content) or bias (e.g., on sensitive historical or political events) on Wikipedia (WP) may have major negative impact on, and potentially be detrimental to, society even when accidental, but even more so in the form of systematic bias through organized manipulation (Shiri, 2017). It is critical to investigate systematic bias on WP to see what kinds of editorial practices contribute to such bias, and if such bias and its "priming effects on audiences" fall into persistent patterns relevant to political or other agendas. "Powerful players devote massive resources to advancing their interests precisely by imposing such patterns on mediated communications" (Entman, 2007, p. 164), and Wikipedia may be no exception.

Such research will help to fill a substantial knowledge gap. It will add new empirical knowledge to debates about social practices of peer production communities, and to conversations about bias and its implications for democracy, particularly in the current context of political manipulation of public opinions on social media and "echo chamber" (or "filter bubble") effects of personalization of online services such as Google and Facebook (Introna & Nissenbaum, 2000; Shiri, 2017). It will shed light on ways to identify WP articles that are affected by systematic conscious bias and on ways to alleviate impact of such bias on the general public, thus helping enhance both traditional (e.g., libraries) and online information services (e.g., Google) in ways that contribute to democracy. After all, exposure to diverse opinions can improve civic discourse and is "one of deliberative democracy's basic tenets" (Sunstein, 2009; Yom-Tov and Boyd, 2014).

This research in progress paper is part of a research program that aims to study systematic conscious bias on WP. It attempts to map the editorial practices of editors who have contributed to articles on Traditional Chinese Medicine (TCM) on WP, and to identify editor groups who have likely committed systematic biased editing. This study could provide evidence to generate empirically-grounded hypotheses concerning various editorial practices that are more likely to be indicative of systematic conscious bias. Two bibliometric methods will be applied: co-authorship analysis and author bibliographic coupling analysis.

Background and related articles

Success and problems of Wikipedia

WP is a system unique in the history of civilization (Simonite, 2013). Both benefits and challenges of the WP system have been widely debated in academia, law, business, and other sectors of society.

WP started in 2001 with the lofty goal of compiling all human knowledge. It grew quickly into the largest encyclopaedia in the world with over 6.8 million registered and uncounted unregistered volunteer editors contributing to 2.3 million articles in the English version alone as of April 2008 (Burke & Kraut, 2008). Many WP articles were of a quality comparable with corresponding ones in Encyclopaedia Britannica as a result (Giles, 2005). WP's success also made it play a symbolic role in highlighting the potential for voluntary peer-production to generate valuable collections of information. Hansen, et al., (2009) even contend that WP "approximates features of the ideal speech situation articulated by Habermas" (Habermas, 1984). With now 5.4 million articles (WP:Statistics), WP has become a one-stop shop for information on most topics. As WP articles often intentionally show up at the top of Google search result lists and are now promoted as fact check sources on Facebook, to name just two prominent examples, WP is clearly a primary information source that people see, and in many cases even the only source that people use.

However, WP's success was to many a surprise. Among the fundamental problems of the WP system that have been criticized are unpredictable motivations of editors and an emphasis on consensus rather than authority (Denning et al., 2005). WP evolves without supervision by certified subject experts or authorities, and its largely anonymous volunteer editors are left to define, interpret and implement its policies and resolve conflicts on their own. WP editors "may be altruists, political or commercial opportunists, practical jokers, or even vandals" (Denning et al., 2005, p. 152). Bias can be introduced and maintained in an article as long as a group of editors with that bias manage to dominate the discussion and force it to a "consensus." Mechanisms used in traditional systems to ensure quality and avoid abuse of power are normally based on true identity along with social expectations, norms, and status positions, and thus cannot work for WP (Arazy et al., 2011).

WP has developed detailed policies and guidelines for contributing and for resolving conflicts, including its two fundamental principles, Neutral Point of View (NPOV) and Verifiability, which intend to ensure all important viewpoints are represented fairly and supported by trustworthy published resources. However, "ironically, Wikipedia rules are often used less to resolve disputes than as tools in waging editing struggles" (Tkacz, 2015, p. 99). A "crushing bureaucracy with an often abrasive atmosphere" formed over the years (Simonite, 2013) where editors would often rely on citing WP policies or threatening to take a matter to ARBCOM (the arbitration committee for dispute resolution) rather than on having a more substantive discussion in resolving conflicts around controversial topics (Koppelman, 2017; Martin, 2017). As a result, "conflicts among editors rarely conclude on the basis of merit but are typically ended by sheer exhaustion, the evident numerical dominance of one group, or admin intervention" (Yasseri, et al., 2012). WP in fact "represents the viewpoint of its most strident and persistent editors" (Hube, 2017, p. 717), some claim.

Admins are considered trusted custodians of WP, and have power to decide if a topic is worthy to cover, to lock articles for targeted editors, and to ban editors (Burke & Kraut, 2008). However, the process of promoting an editor to admin has been found susceptible to manipulation, and, once an admin, they are mostly free to exercise the power at will as there are few measures to hold them accountable (Picot-Clémente, et al., 2015).

Anecdotal evidence of manipulation and systematic conscious bias on WP has been reported in the literature. Organizations with strong beliefs such as "Guerilla Skeptics on Wikipedia" have been accused of persistently maintaining WP articles of their interests to promote their own viewpoints (Koppelman, 2017; McLuhan, 2013). Research has found that some editors have likely sought admin power in order to change and control discussions regarding controversial topics of their interest (Das et al., 2016). There is evidence for "covert editing efforts to shape the portrayal of individuals, organizations, and topics" (Craver, 2015; Thompson, 2016), and for "systematically biased editing, persistently maintained," to impose certain viewpoints on controversial topics such as vaccination (Lih, 2009, pp. 122-131).

Studies on bias and controversy on Wikipedia

Studies from different perspectives both about WP and using WP as data are abundant (Yasseri, et al., 2012). These studies were possible partly because nearly all edits and discussion posts are saved and available on WP. Directly related to the present research are studies on bias and controversy.

Bias has been extensively studied in the context of media as biased news can influence power distribution and hurt media's contribution to democracy (Entman, 2007). Based on the research concept "bias" defined there, studies on bias on WP, including political bias (Greenstein & Zhu, 2012), cultural bias (Callahan & Herring, 2011), and gender bias (Graells-Garrido, et al., 2015), have mostly focused on "content bias" – "favoring one side rather than providing equivalent treatment to both sides" in a conflict.

Bias on WP is often related to controversial topics. Studies on controversy on WP have largely focused on automatically detecting them, e.g., by identifying "edit wars" in the form of mutual reverts (e.g., Hube and Fetahu, 2018; Yasseri, et al., 2012). Most studies targeted articles; only a few targeted editors, as does the present study. Liu & Ram (2011) studied the impact of editor collaboration patterns on article quality. They found that clustering editors by features extracted from their editing activities is a highly promising method for characterizing editing behaviours and collaboration patterns. For example, they found Watchdogs and Cleaners, i.e., editors focusing on reverts and removing materials respectively. Das et al. (2016) proposed and validated two controversy scores in an attempt to identify "manipulating editors," i.e., editors who changed their editing behavior to focus on controversial articles in a single topic area after gaining admin status. They measured topic similarity between two WP articles by a combination of the degree to which they share references, linked terms, and WP topic categories. We use and explain some of these methods in the Methodology section.

Methodology

Overview and assumptions

We will first identify and download articles on TCM from WP. We will then examine the editorial practices of editors who have contributed to these articles. We will finally identify editor groups who have likely committed systematic biased editing.

Drawing on previous studies, we assume that editors who have likely committed systematic biased editing are editors who feature the following editorial practices.

(1) Peculiar editing behaviors. To bias an article, editors are expected to exhibit different styles of contributing to WP compared to normal editors. They might constantly monitor and act quickly to "protect" articles of their interests whereas others may contribute irregularly based on their work/life schedule (Sundin, 2011). They would rely heavily on citing WP rules and banning resisting editors through admins to avoid consensus building processes whereas

normal editors may be more interested in contributing ideas and fixing problems than learning about the nuances of WP rules (Koppelman, 2017). They would often revert edits (Martin, 2017) while normal editors tend to simply add new materials and viewpoints. They tend to spend most of their time on a small number of contested topics (Das, et al., 2016).
(2) Lasting group support. Conflicts among editors are typically ended by "sheer exhaustion, the evident numerical dominance of one group, or admin intervention" (Yasseri, et al., 2012). To bias a controversial article in the face of resistance, a number of editors sufficient to dominate the discussion must gain support from each other, and/or from admin(s) who can overrule resisting editors (Martin, 2017). Such a support structure will likely be in place in many articles to dominate an entire topic area.
(3) One-sided selection of information sources. This is a technique used to introduce bias into an article (Martin, 2017). To bias articles systematically and to meet WP's verifiability requirement at the same time, organizations or groups of editors would likely develop a core set of information sources that support their views and use them in all articles of their interest.

Data collection and analysis

To this end, we will adapt and follow the well established procedures and techniques for co-authorship analysis and author bibliographic coupling analysis. Instead of a citation database, we will use the English version of WP as data source, and will develop computer programs to collect and analyze data from WP. Instead of multivariant analysis methods such as cluster analysis or factor analysis, we will use community detection techniques to accommodate the large number of editors to be examined. We will use InfoMap, an open-source community detection algorithm recommended for identifying meaningful communities with stronger internal than external connections in networks of up to 6000 nodes (Yang, et al., 2016).
(1) Download dataset and select editors to examine
We will identify articles on TCM by starting with the articles on TCM proper or in the WP categories of TCM therapies or TCM medical plants, and then adding articles interlinked heavily with these seed articles. We will download all these articles from WP, including the entire editing and discussion history of each article. We choose the topic area TCM for this initial test because it has been reported that this area has been affected by systematic biased editing as one of the public targets of the "Guerilla Skeptics on Wikipedia" (Koppelman, 2017; McLuhan, 2013). Since biased editors are likely frequent contributors, we will exclude editors who have not contributed frequently to these articles.
(2) Characterize editing behaviour
For this, we will examine editing features on both the articles themselves and on their associated Talk pages. The former will include the features used in Liu & Ram (2011), i.e., insertion, modification, or deletion of text, link, or reference. The latter will include number of reverts, WP rule citation (R), taking (or threatening to take) a matter to ARBCOM (A), or suggesting banning of resisting editors (B). We will also include the two controversy scores introduced and tested in Das et al. (2016): a Controversy (or C-) score indicates the degree to which an editor focuses on controversial articles, and a Clustered Controversy (or CC-) score captures the degree to which an editor focuses on a particular controversial topic (in this case, TCM). We will build an editing profile for each editor, which includes these features, and, by analyzing these profiles using InfoMap, will identify communities of editors that are densely connected through common editing behaviour patterns. We will compare editing behaviours of those communities that are characterized by high R, A, B, C, and CC scores with other communities. We will determine if the articles that these featured communities have contributed to heavily belong to the same topic areas, and, if they do, will also determine if bias exists in samples of these articles through close reading.
(3) Characterize editors' co-involvement patterns

Following co-authorship analysis techniques, for each pair of editors selected above, we will compute the number of articles (N) they are both involved in, either on the articles themselves or on their associated Talk pages. We will also weigh this number by the level of their involvement in each article. For example, if editors A and B have made n and m substantial contributions respectively to an article, this article will increase their weighted co-involvement score by min(n, m), i.e., the smaller one of the two values. All the N articles will be counted this way to arrive at the total weighted co-involvement score for A and B. As a result, two K x K matrices of co-involvement scores will be produced, with K being the number of editors selected to be examined: simple and weighted. We will identify communities of editors that are densely connected through their co-involvement patterns by analyzing these matrices using InfoMap. We will then compare co-involvement patterns of those communities that overlap heavily with communities of editors identified above that are characterized by high R, A, B, C, and CC scores with other communities.

(4) Characterize editors' referencing behaviour

Following author bibliographic coupling analysis techniques, a matrix of shared reference scores will be produced for all selected editors. If editors A and B have contributed substantially to article sets S1 and S2 respectively, and n different information sources were cited in both S1 and S2, n would be the shared reference score for A and B. We will identify communities of editors that are densely connected through shared references by analyzing this matrix using InfoMap. We will then compare referencing features and preferences of those densely connected communities that overlap heavily with communities of editors identified above that are characterized by high R, A, B, C, and CC scores with other communities.

Expected major results

We expect to see heavy overlaps between communities of editors that are characterized by high R, A, B, C, and CC scores, and those that are densely connected through co-involvement and shared reference patterns. Bias is expected to exist in articles that these featured communities have contributed to heavily, and clear topical themes should emerge from these articles, indicating that these topic areas have been biased systematically.

Bias in Academic Recruitment: the Italian National Scientific Habilitation

Marco De Santis Puzzonia, Irene Mazzotta and Sandro Momigliano

Abstract

Since 2012, access to university calls for associate and full professorship in Italy is restricted to candidates who passed a national fit-for-the-role evaluation, the National Scientific Habilitation (NSH). NSH Committees evaluate candidates considering the importance, quality and originality of their publications, granted awards, received funds and membership of scientific boards. We analyse the relationship between the decisions taken by the Committees and the quality of the scientific production of candidates, by using a polynomial probit model. We also test the impact of two specific factors, gender and affiliation, on the probability of success. Relatively small effects have been detected with regard to the candidates' gender; furthermore, in Humanities and Social Sciences women are generally favoured. As for the affiliation factor, an outsider status is associated to drastically lower probabilities of success. This result may however reflect a number of factors not considered in this analysis, whose results are thus only a first step in the direction of understanding whether it exists or not an "affiliation" bias in the NSH.

Introduction

Since 2012, the Italian university recruitment of associate and full professors follows two steps: a national fit-for-the-role evaluation, the National Scientific Habilitation (NSH), and local (university) level contests, restricted to "habilitated" candidates. Habilitation is awarded by NSH Committees, one for each of 190 disciplinary fields ("Settori Scientifici", SC) identified within 14 areas. NSH Committees evaluate only eligible candidates, i.e. candidates who satisfy pre-determined requirements concerning their publication record.[1] More specifically, candidates must meet or exceed at least 2 out of 3 SC-specific thresholds. In STEM areas[2] the thresholds refer, for given time intervals, to 3 indicators: the number of articles, citations received and the h-index value. In the Humanities and Social Science areas[3], they refer to the number of articles and book chapters, articles in A-ranked journals, and books (for a more thorough description of the procedure, see Bagues et al., 2017).

At the start of the NSH "rounds", in 2012, 2016 and 2018, based on specifications by the Ministry of Education (MIUR), the Agency for the Evaluation of the University and Research System (ANVUR) calculated the thresholds for each SC, separately for candidates to Associate and Full Professor positions.[4] In 2016, these thresholds meant that, in each SC, about 2/3 of the associate professors (AP) and researchers were eligible candidates for a full professor (FP) and an AP position, respectively. Following the selection carried out by ANVUR, in 2016-18 the National Committees evaluated the eligible candidates on the basis

[1] In the first NSH round (2012-14), Committees could choose to admit to evaluation individual candidates which did not satisfy the minimal requirements, but had to explicitly motivate the decision.

[2] They include the following areas: Mathematics and Informatics; Physics; Chemistry; Earth Sciences; Biology; Medicine; Agricultural and Veterinary Sciences; Civil Engineering and Architecture; Industrial Engineering and Information Systems.

[3] They include the following areas: Classical studies, Philology, Arts and Literature; History, Philosophy and Psychology; Law; Economics and Statistics, Political and Social Sciences.

[4] The thresholds were published in the Ministerial Decree n. 602/2016 (http://attiministeriali.miur.it/anno-2016/luglio/dm-29072016.aspx).

of the following elements: importance, quality and originality of their publications according to the disciplinary field, granted awards, received funds and membership of scientific boards[5]. The aim of this paper is to investigate: a) the relationship between the decisions taken by the NSH National Committees and the quality of the scientific production of candidates; b) whether this relationship changes depending on gender and on candidates being inside or outside the Italian academic community. Underrepresentation of women in medium and high ranks of academic careers is internationally documented, and Italy is not an exception (Fig.1)[6]; stimulated by this evidence, a large literature on gender bias in academic promotions has developed (Ceci et al., 2014; Morley, 2014; European Commission, 2015; OECD, 2018). The Italian case is particularly interesting because the NSH introduced in 2012 was meant to correct allegedly widespread favouritism (likely to include a gender bias) in the previous recruitment and promotion system. While there is relatively clear evidence of gender bias in local contests (Marini and Meschitti, 2018; De Paola and Scoppa, 2015), the existence of discrimination against women in the NSH process is more controversial. In particular, De Paola, Ponzo and Scoppa (2015) do not find evidence of discrimination, while Bagues et al. (2017) document the existence of a significant gender bias. Evidence concerning possible biases in recruitment/promotion against outsiders of the academic community is relatively scanty. The main difficulty here is the fact that candidates are typically evaluated, not only on the basis of their scientific production, but also on a number of other features, some of which are difficult to gauge (Pezzoni et al., 2012; Xuhong, 2014). Typically, insiders tend to be stronger in these additional elements included in the evaluation; for example, though it is not the case of Italy, teaching experience is explicitly included. As in the following preliminary analysis we are not able to control for these additional factors, the results have to be considered only as a first step in the direction of understanding whether there exists an "affiliation" bias in NSH. Evidently, a better knowledge on the issues of gender and affiliation bias would represent an important input in the discussion for further reforms of the regulation of the Italian recruitment system.

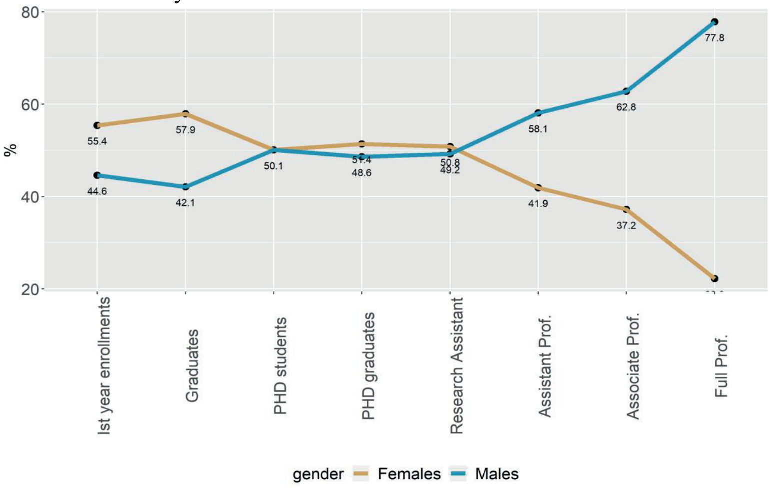

Figure 1. Percentage of females and males in the Italian academic rank in 2016
Source: ANVUR (2018); Chapter I.3.4; page 273. Translation by the authors.

[5] A detailed specification of the elements to be considered in the evaluation carried out by the National Committees is contained in the Ministerial Decree n. 76/2012.

[6] Chapter II.11.4 in ANVUR (2018) provides some analyses on gender-related issues in the Italian University system.

Data

Our initial dataset includes 28,942 eligible applications for Associate and Full professor assessed by the NSH Commissions in the period 2016-18 (2016 round).

To analyze affiliation, we consider as "insiders" Full Professors (FP), Associate Professors (AP) and Assistant Professors ("Ricercatori": formerly permanent staff, since 2010 new recruits are under fixed-term contracts) in Italian Universities. Everybody else is classified as "outsider", including professors working abroad and researchers working in Italian Universities with other positions (e.g. PhD fellows, post-doctoral fellows and fixed-term research assistants).

As a proxy of the quality of the scientific production of candidates, we use the h-index value, for STEM areas, and the number of publications in A-ranked journals, for Humanities and Social Sciences[7]. To standardize the indicators across SCs, we divide each value by its SC-specific threshold used for the initial screening of candidates (see above). The distribution of candidates across values of the quality indicator is broadly similar for males and females and for insiders and outsiders (Figures 2 and 3).

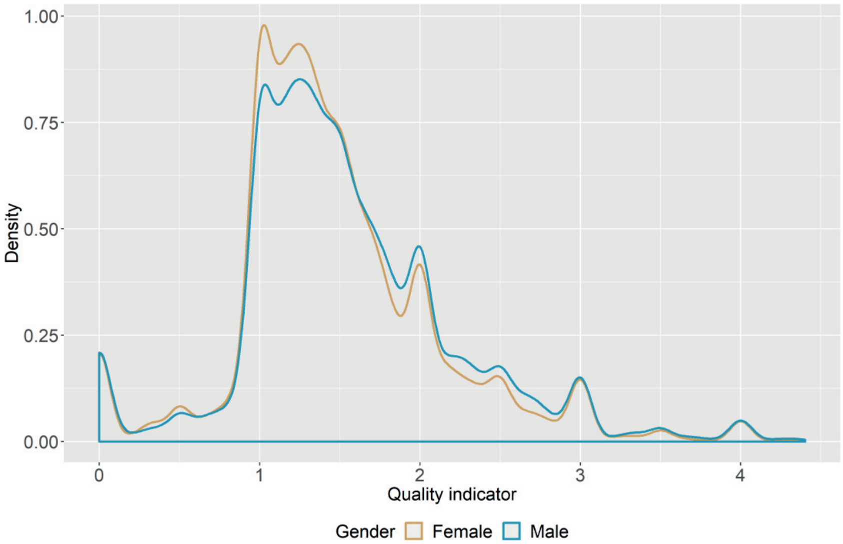

Figure 2. Density of the quality indicator distribution by gender

[7] These indicators were calculated, for each AP candidate, over 10 years and FP candidate over 15 years period.

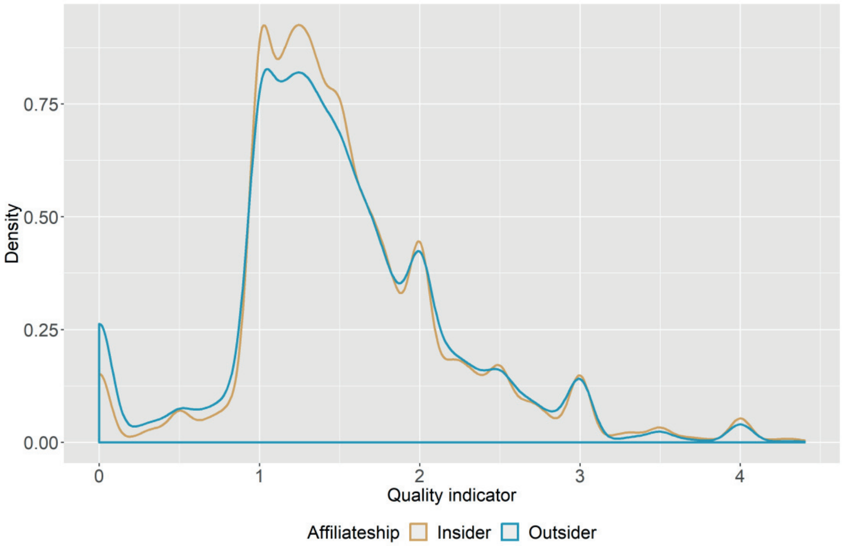

Figure 3. Density of the quality indicator distribution by affiliation

We exclude candidates with extremely high values for the indicator of quality. In particular, in STEM areas we exclude candidates with values higher than 3 times the admission threshold (about 4% of candidates). As this would imply excluding too large a number of candidates in HSS areas, there we exclude those with values above 4.4 times the admission threshold (10% of candidates). Overall, excluding outliers, we considered in our analysis 27,403 individual observations. We study the impact of gender and affiliation separately[8]. Each analysis is carried out in 4 separate cases: distinguishing between STEM and HSS areas and between the two positions for which the habilitation is sought (AP or FP; Table 1).

Table 1. Frequencies and % of success of candidates, by areas and academic rank (excluding outliers).

	HSS areas		*STEM areas*	
	Male	*Female*	*Male*	*Female*
Full Prof.	1388 (56,9%)	753 (62,2%)	5235(59,7%)	2202(61,3%)
Associate Prof.	2249 (49,1%)	1613 (59,6%)	8162 (55,5%)	5801 (53,2%)

	HSS areas		*STEM areas*	
	Outsider	*Insider*	*Outsider*	*Insider*
Full Prof.	278 (26,5%)	1863 (63,7%)	1525 (42,8%)	5912 (64,7%)
Associate Prof.	1949 (38,3%)	1913 (66,7%)	7539 (44,3%)	6424 (66,6%)

[8] The separate analysis is warranted by the very low correlation (r=0.006) which exists between the two characteristics.

The relevant data are as follows: we consider whether the candidate belongs to STEM or HSS areas, the value of its quality indicator, the gender, the position for which the habilitation is sought, the affiliation, and the outcome of the evaluation.

In estimates not provided here, we also considered as control variables, the age of applicants and a proxy for quantity of publications (the number of articles, for STEM, and the number of articles and book chapters for HSS areas). The evidence of their impact is not robust, as the significance depends on the specific setting: for example, age is never significant when analysing gender, and the quantity indicator is only significant when analysing affiliation in evaluation of AP in STEM areas. Moreover, the inclusion of these two variables does not modify in an appreciable way the results produced below (estimates with the extended model available on request).

The model

To explore the impact of gender and affiliation on the probability of success in the NSH, we estimated the same following probit model:

$$P(y=1) = F\,(\beta_0 + \beta_1\,x + \beta_2\,z + \beta_3\,z^2 + \beta_4\,z^3 + \beta_5\,z^4 + \beta_6\,xz + \beta_7\,xz^2 + \beta_8\,xz^3 + \beta_9\,xz^4) \qquad (1)$$

where y is the binary outcome variable, x is the binary variable representing either the affiliation or the gender (equal to 1 for insiders and males, respectively), z is our quality indicator, F is the cumulative distribution function of the standard normal distribution and P is the probability of success. The use of the polynomial to the 4th power for z reflects preliminary estimates, which suggested that a linear model was not appropriate, both in STEM and HSS areas. In particular, in a probit model for STEM areas (including both AP an FP candidates) coefficients were significant until the 4th power, while in HSS areas until the 2th. For homogeneity of analysis, we decided to adopt the same model (polynomial at 4th power) in both cases.[9] In the variables associated to coefficients from β_6 to β_9 we make z and x interact, allowing the latter to impact on the shape of the probability curve, not simply to shift it.

In the Appendix, together with the benchmark model detailed estimates (Tables A1 and A2; columns 1, 3, 5, 7), we present the (broadly similar) results of an alternative specification where we consider as control variables the individual areas respectively included in STEM and HSS (Tables A1 and A2; columns 2, 4, 6, 8).

Results

Gender

Figure 4 shows the estimated probability of success associated with different values of our proxy for quality of publications, distinguishing by gender. Each sub-diagram refers to one of our 4 cases, as we apply our model separately for STEM and HSS areas and for the position sought (AP and FP). In Appendix we present the full results of the probit estimations.

As for the shape of the relationship outlined in the sub-diagrams, it is clearly different in STEM areas with respect to HSS areas. In the former, it is clearly S-shaped: H-index values which are below half of the threshold are associated to a nihil probability of success; in the range 0.5-1.5 the curve is steep, and probability rises at 60%; afterwards it is mainly flat, suggesting that higher values do not have an additional impact on the NSH Commissions' assessment.

[9] Excluding the 3rd and 4th power for HSS does not modify in an appreciable way the results.

In HSS areas, even in the absence of publications in A-ranked journals,[10] there is a significant probability of success (30%); the latter increases mildly as the value of our quality indicator rises, reaching values at the end of the distribution which are close to 80% for AP and 60% for FP.

Figure 4 shows relatively small differences between males and females, more evident in the case of HSS areas, where they are generally in favour of women. In Table 2 we report the results of a χ^2-test concerning the joint significance of the coefficients ß$_1$ and from ß$_6$ to ß$_9$. They indicate that the shape of the relationship between the quality indicator and the probability of success is significantly influenced by gender only in the case of AP (top sub-diagrams in Figure 4).[11] As for the actual impact on estimated probability, in the case of AP it is on average 8% for HSS in favour of women and 2% for STEM, in favour of men (Table 3).

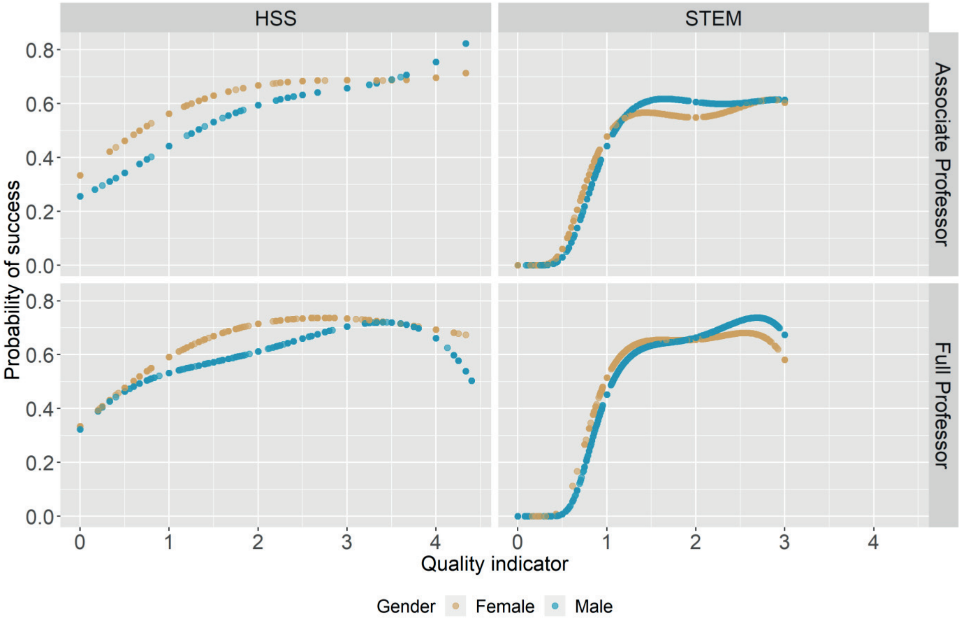

Figure 4. Estimated probability of success by scientific field and gender

Table 2. The χ^2 statistics for ß1, ß$_6$ - ß$_9$ coefficients

		HSS areas				*STEM areas*		
		full prof.		*associate prof.*		*full prof.*		*associate prof.*
Gender		0,0711		0,0000		0,0851		0,0003

[10] In this case, evidently, the candidate had met or exceeded the thresholds for the other 2 requirements (articles and book chapters, books).

[11] The result of the test for FP in HSS may also reflect the relatively small number of observations.

Table 3. Differences in estimated probability: males-females

Accademic rank	*Male-Female Probability at the median*		*Male-Female Average Probability*	
	HSS areas	*STEM areas*	*HSS areas*	*STEM areas*

Full professor	-0,10	-0,02	-0,05	-0,02

Affiliation

Figure 5 shows the estimated probability of success associated to different values of our proxy for quality of publications, distinguishing by affiliation. In Appendix we present the full results of the probit estimations. Also in this case, the shape of the relationship outlined in the sub-diagrams is different in STEM areas with respect to HSS areas, though differences are not as clear-cut as in Figure 4. The main evidence here is the large difference, for almost any given levels of our quality indicators, in the probability associated to insiders vs. outsiders. In particular, in HSS areas, even in the absence of publication in A-ranked journals, insiders have a probability of success of 50%, while the probability for outsiders is 0 for FP and about 10% for AP. Moving to the higher levels of quality, the difference decreases but remains large in both cases. In STEM areas, low levels of H-index are instead associated to a nihil probability of success for both insiders and outsiders, but a large difference in the probability between the two groups emerges for higher values. In Table 4 we report the results of a χ^2-test concerning the joint significance of the coefficients $ß_1$ and from $ß_6$ to $ß_9$. They indicate that the shape of the relationship between the quality indicator and the probability of success is significantly influenced by affiliation in all analysed cases. As for the actual impact on estimated probability, on average it ranges from 22% for FP to 37% for AP in STEM areas (Table 5).

Associate professor	0,24	0,21	0,28	0,37
Full professor	0,20	0,21	0,22	0,22

Conclusion and discussion

This paper contributes to the debate on gender discrimination in Italy and provides a preliminary analysis of the issue of bias against outsiders of the Italian Academia.
We focus on the decisions taken by the National Scientific Habilitation Committees – the first step in the Italian university recruitment of associate or full professors – and investigate whether the relationship between these decisions and the quality of the scientific production of candidates changes depending on gender and on candidates being inside or outside the Italian academic community.

As for the gender factor, we find relatively small differences between males and females in the relationship between the probability of success and our proxy for quality of publications. For candidates applying for a position as an Associate Professor, a $\chi 2$-test on the gender coefficients shows that these differences, albeit quantitatively small, are statistically significant, in HSS areas in favour of women, in STEM areas in favour of men. For candidates applying for a position as Full Professors, possibly due to the relatively small number of observations, the differences (in both cases in favour of women) are not significant. We interpret these data as an evidence that transparency in the NSH process limits gender discrimination to isolated cases, if any. The question remains whether this balanced assessment will eventually produce a drastic reduction of the large gender gap which exists in medium and high ranks of academic careers, or if it will be substantially undone by the second, decisive step in the recruitment/promotion process, the local contests.

As for the affiliation factor, our analysis shows that an outsider status is associated to drastically lower probabilities of success in the NSH, for all levels of our quality of publications indicator, regardless of which position or disciplinary area candidates apply for. This result, however, may reflect factors other than discrimination. As already pointed out, insiders may be stronger in some of the additional elements included in the evaluation – such as granted awards, received funds, and membership of scientific boards – which the Committees are explicitly required to take into account. The difference could also be explained by the specialization in the field of study. Insider candidates could be more able to meet the requirement of coherence with the disciplinary field they apply in. Since we could not control for these additional factors, the results of our analysis shall be considered only a first step in the direction of understanding whether it exists or not an “affiliation” bias in the NSH.

Acknowledgments

We are grateful to the Ministry of Education and CINECA, for providing the dataset of the applications to the National Scientific Habilitation, and to Alessandro Palma for helpful comments.

Augmenting a Research Information System with automatically acquired category and keyword information

Sven Blanck, Andreas Niekler and Marc Kaulisch

{marc.kaulisch,sven.blanck}@zv.uni-leipzig.de, aniekler@informatik.uni-leipzig.de
Leipzig University, Ritterstraße 26, 04109 Leipzig (Germany)

Abstract

With an ever-increasing amount of data, it is essential for many systems that documents can be retrieved efficiently. The process of information retrieval can be supported by metadata enrichment of the documents. The aim of this work is to make scientific publications and project descriptions, consisting of titles, abstracts and bibliographical references, easier to find. Therefore, we investigate text analytical methods such as keyword extraction algorithms (TFIDF, Log-Likelihood, RAKE, TAKE and KECNW) and classification approaches using a SVM with ensembles of classifier chains (Web of Science and GEPRIS categories as taxonomies) and compare their quality. We present an altered an optimized keyword extraction algorithm and a supervised subject and keyword classification approach which are, to our knowledge so far, one of the first automatic applications of this kind in informetrics and scientific information retrieval.

The most promising methods are employed and the extracted information is attached to the documents as metadata. These support a search query, using pseudo relevance feedback, to obtain further relevant search results and can also be used to derive profiles for authors, faculties, etc. The concepts developed here will serve as a basis for the Leipzig University Research Information System.

Introduction

In this paper, we present an evaluation of methods used in Natural Language Processing and Text Mining in order to generate unified keywords, classify projects and publications and improve findability of research information. Our aim is to develop a (semi-) automatic annotation approach for research information, which provides a standardized and unified way to augment this information with additional metadata such as keywords and classifications.

The self-developed Leipzig University Research Information System (leuris) targets metadata about projects, publications, prices/awards, international research partnerships, academic events, patents, transfer activities and researcher education. In each information entity, the text data such as titles, abstracts or full-texts are collected. Leipzig University aims to use this text data threefold. First, this text data is analysed in order to profile research at Leipzig University internally. Second, text data analysis improves the findability of research information for external and internal purposes. Third, the utilization of text data enables content-based classification in order to ease further internal analysis and to display annotated research information users of the information system.

Keywords or subject areas are important metadata of research projects, research proposals, conference contributions or journal articles. However, each publisher, funder or conference organizer might use a different subject category system and often leaves the keyword selection decision to the authors. Within a Current Research Information System (CRIS), this leads to a heterogeneous and large set of keywords and subjects in large collections of documents. This ultimately results in ambiguous keywords which make it hard for a CRIS to use such information for performant and effective searches. However, these manually assigned keywords can be used as metadata to optimize a CRIS – not only for search tasks but also for classifying research activities – in addition to automatically extracted keywords and classes.

In the literature there are essentially two different ways to automatically generate keywords from a given text (Beliga, Meštrović, & Martinčić-Ipšić, 2015). The first type is keyword extraction. This weights the terms that appear directly in the given text according to their importance and sets the most important ones as keywords as they declare the documents main contents. The second approach is keyword assignment. We assess the problem of keyword

assignment with the automatic classification of given category schemes as it might be difficult or impossible to create, maintain and extend a controlled uniform technical vocabulary for multiple disciplines (Singhal, Kasturi, & Srivastava, 2013). Therefore, we decided to evaluate individual methods for keyword extraction and keyword assignment. We assess the problem of keyword assignment with the automatic classification of given category schemes.
The novelty of our contribution is the alteration of known approaches to fit scientific publications or scientific texts. In detail, we changed term weighting schemes and score aggregation functions of the underlying algorithms and evaluated their results in order to fit the methods to the here described text sources. Additionally, we present a supervised subject and keyword classification approach which is, to our knowledge so far, one of the first applications of this kind in informetrics and scientific information retrieval.

Related Work

In this paper we present a Text Mining-based approach to extract full-text-based meta-information. This information will later be used in information retrieval tasks within leuris. Information retrieval and informetrics are symbiotic fields (Wolfram, 2015). In scientometrics/informetrics fields text analysis and information retrieval is among other things used for topic clustering and finding possible specialities (Sjögårde & Ahlgren, 2019).
For some time now, statistical methods of keyword extraction have offered the best results with regard to precision, recall and F1 score. Approaches such as TF-IDF (Sparck Jones, 1972) and Log-Likelihood (LL) (Rayson, Berridge, & Francis, 2004) use a reference corpus to rank individual terms. Especially the TF-IDF measure is popular as a baseline to compare and evaluate new algorithms. Up to this point, it is the workhorse in many applications such as the Solr/Lucene full-text index.
Another group of keyword extraction approaches is graph-based. As stated by Beliga et al. Graph-based approaches represent a good alternative to statistical approaches due to their independence from linguistic knowledge, domain and language (Beliga et al., 2015). Part of this work is aimed at evaluating the results of statistical methods with graph-based methods such as RAKE (Rose, Engel, Cramer, & Cowley, 2010), TAKE (Pay, 2016) and KECNW (keyword extraction using collective node weight) (Biswas, Bordoloi, & Shreya, 2017), which is a further development on TextRank (Mihalcea & Tarau, 2004) and NE-Rank (Bellaachia & Al-Dhelaan, 2012). While statistical and graph-based methods arrange the individual terms according to their relevance, RAKE and TAKE also employ methods for multi-term keyword candidate recognition using linguistic knowledge (Hulth, 2003). We apply the strategies, which create multi-term keyword candidates to the other approaches (KECNW, TF-IDF, LL) as well.
Our second approach, a supervised classification of scientific categories, has originally been described in (Brück, Eger, & Mehler, 2016; Uslu, Mehler, Niekler, & Baumartz, 2018; Waltinger, Mehler, Lösch, & Horstmann, 2009). In this work, the authors describe a classification mechanism using the word contents of short text snippets in order to assign a DDC category to each of the short texts. The authors utilize a Support Vector Machine (SVM) to classify the text snippets. Uslu et al. (2018) extend this approach by combining a SVM and a Neural Network Classifier with only a slight performance gain and we therefore stick to the original approach and will use only SVM classification for ease of understanding. However, a SVM is normally only responsible for assigning one label to a text. In our case, we need to assign multiple labels to a single document that will act as categories in later applications. One problem transformation that has proven to be practical is One-vs-Rest classification also referred to as binary relevance (BR) (Aly, 2005). Label relations amongst each other can be integrated into the learning process of a SVM with the help of classifier chains (CC) (Read, Pfahringer, Holmes, & Frank, 2009). A further improvement are ensembles of classifier chains

(ECC), which minimize the risk of a poorly chosen classification order through multiple iterations of CC and majority voting (Read, Pfahringer, Holmes, & Frank, 2011).

In our work, we use the extracted metadata consisting of keywords and categories to expand search queries and hence improve the performance of retrieval systems. As Xu & Croft (1996) confirmed in their experiments, an expansion with local feedback based on the search results of the original query is more suitable than global techniques that examine word relationships in a corpus. Therefore, the application examples in this paper use an expansion with local feedback called Pseudo Relevance Feedback (PRF), as this technique currently represents the state of the art (Ariannezhad, Montazeralghaem, Zamani, & Shakery, 2017; Keikha, Ensan, & Bagheri, 2017).

Datasets

In this paper, we are investigating methods to extract keywords and classify research information into suitable classifications on the basis of scientific abstracts. In order to do so, we need to utilize different datasets for training and testing. We used a suited dataset to evaluate the keyword extraction methods. For this purpose, we acquired a dataset from the Web of Science, which contains examples of the category *Computer Science, Interdisciplinary Applications* in order to design and evaluate the keyword extraction algorithms. Based on the assumption that there is a good chance to get meaningful keywords in the field of computer science the decision fell on this specific category. Each example in this dataset contains the title, abstract, references and a set of keywords chosen by the authors. Since the presented methods can only find keywords that are directly in the title or abstract, all author keywords that are not directly contained in the title or abstract are ignored for further evaluation. In order to avoid filtering out different inflections the titles, abstracts, bibliographical references and authors keywords where lemmatized. We use only publications with more than three keywords and out of the 1056 initial examples, 603 remain for our evaluation purposes.

We chose datasets from the Web of Science and the German Project Information System[1] to create and evaluate subject classification models. For the evaluation of the project abstract classification in German, the GEPRIS taxonomy[2] was used, which consists of four granularity levels. We had no access to a dataset containing the fourth level. Hence, only the first three levels where used in the category classification experiments. The GEPRIS dataset consists of the title, the project description and the corresponding category from the GEPRIS taxonomy. The datasets divide into the three levels as follows:

- First Level: 46547 examples, 4 categories
- Second Level: 46547 examples, 14 categories
- Third Level: 28712 examples, 48 categories

We used the Web of Science taxonomy[3] for the evaluation of publication abstract classification in English. To assign proper categories to the acquired dataset a publication automatically gets a category assigned depending on the journal in which it was originally published. Additionally, the CWTS Leiden main fields[4] provide broader topics and can easily be mapped from the Web of Science categories. This works for all but three of the Web of Science categories, which have no mapping yet. Each of the examples contained in the dataset consists of the title, the abstract, the bibliography and the corresponding category from either

[4] Leiden main fields, http://www.leidenranking.com/information/fields

the Web of Science or the CWTS Leiden taxonomy.
We divided the dataset as follows:

- Web of Science categories: 44866 examples, 254 categories
- CWTS Leiden main fields: 42110 examples, 5 categories

As a last step we applied our evaluated methods to different datasets based on publication and project abstracts derived from the Leipzig University Research Report[5] and inserted the results into a SOLR index.

Keyword and Phrase Detection

In general, all keyword extraction algorithms presented in the related work use a score calculation for the individual terms (unigrams) to determine their relevancy within the document. RAKE and TAKE additionally use methods to extract multi-term keyword candidates from the text and rank them by using the sum of the individual term scores. We assume that the presented keyword extraction methods can be divided into three sections:

1. Keyword candidate extraction
2. Score calculation of the individual terms
3. Ranking of the keyword candidates

Keyword candidate extraction

The approaches from RAKE and TAKE were used for the candidate extraction. In short, RAKE uses a stopword list to divide a text into word sequences and uses them as candidates. The original TAKE approach uses Part-of-Speech Tags to extract noun chunks with eventually co-located adjectives from the text. This approach is based on Hulth's studies which show that linguistic knowledge with noun chunks achieves better results in a keyword extraction process than the simple use of n-grams (Hulth, 2003). Our program extracts the candidates from the title and the abstract, which are combined into one single text using a full stop as sentence separator. The bibliographical references will be used later to calculate the individual term scores. SpaCy (Honnibal & Montani, 2017) is used as a POS tagger and lemmatizer for TAKE and we used a stopword list as a separation feature for RAKE.

Score calculation of individual terms

To calculate the score we tested several methods. These include the statistical approaches TF-IDF and the Log-Likelihood-Ratio. We also tested the graph-based methods KECNW and RAKE respectively TAKE, which are both based on the same principle. In addition, the evaluation includes a combination of TF-IDF and KECNW, which will be discussed later.
In TF-IDF, the individual words are arranged in descending order according to their relevance and the n-best are used as keywords. Note, the IDF value is obtained from the reference corpus. The Log-Likelihood-Ratio uses two corpora to calculate the keywords. The first corpus is the corpus to be examined and the second serves as the reference corpus. Basically, the method carries out a statistical significance test if a selected keyword differs from its statistical expectation. The Log-Likelihood-Method was developed based on the Chi-Squared-Test. The Chi-Squared-Test is based on a normal distribution for statistical text analysis. As an alternative for short texts Dunning suggests the Log-Likelihood-Ratio (Dunning, 1993). This ratio is not based on the assumption that statistical textual analysis is a normal distribution and assumes a binomial and/or multinomial distribution. We simply calculate the RAKE / TAKE (RaTa) based score by the degree of a word divided by its occurrence frequency within a document. The degree is the number of co-occurrences with other words within a specified window in a single document. In the evaluation, a window size of 2 was chosen. KECNW is another algorithm for

[5] Leipzig University Research Report, https://fob.uni-leipzig.de/#/welcome

the automatic extraction of keywords, which was developed especially for Twitter data and based on the ideas of PageRank and TextRank. KECNW is divided into four phases: Textual pre-processing, building a graph structure, node weight assignment and keyword extraction. Each token in the texts will be become a node in the resulting graph structure. An additional filtering is applied by deleting all words which do not exceed the Average Occurrence Frequency (AOF). The edges are formed at words that directly adjoin each other in a sequence. The weighting of an edge is determined by the co-occurrence frequency of a term *i* and a term *j*, as well as their individual frequencies. In the next step, the nodes are weighted. The weighting is composed of five different components: Distance to the central node ($D_{C(i)}$), selectivity centrality ($SC(i)$), importance of neighbouring nodes ($Neigh_{Imp}(i)$), position of a node ($F(i), L(i)$) and term frequency ($TF(i)$). These values are normalized for further calculation. For details on the formulas please refer to the original paper (Biswas et al., 2017). We alter the formulas later but leave out the calculation details for reasons of compactness. Since KECNW is designed for the analysis of Twitter texts (tweets, very short), it is necessary to alter the algorithm for scientific texts. In detail, we exchanged the pre-processing and the additional weighting of the first and last word in the text. We simply, in the case of scientific texts, weighted the first and last words from the title and abstract ($F(i), L(i)$). An additional weighting of the first and last words in the literature references was omitted, since these have only a supporting function and should not influence the result excessively. In addition, we experimented with several parameters. The AOF which must be used according to the original KECNW algorithm is ignored because the abstracts are short texts and possibly important words, which occur only once, are omitted. As our experiments confirmed, omitting the AOF did indeed improve the results for our short documents.

The TF-IDF and the Log-Likelihood-ratio computation needed a comparison corpus. We choose a collection of 1 million sentences of the English Wikipedia of the year 2016 made available by a project within Leipzig University (Uwe Quasthoff & Eckart, 2015). These sentences are lemmatized and brought into a bag-of-word representation.

In addition to the normal KECNW approach, the following modifications were tested:

- *KECNW-Trigram* does not only use the direct neighbours, but also the neighbours of the neighbours as edges.
- *KECNW-Sentence* uses all words that occur in the same sentence as edges.
- *KECNW_multiply_idf* additionally uses the IDF for the node weighting. The modified node weighting function looks as follows:

$$Node\_weight(i) = (D_{C(i)} + SC(i) + Neigh_{Imp}(i) + F(i) + L(i) + TF(i)) \cdot \text{ IDF(i)}$$

- *KECNW_use_tfidf* also uses the IDF from the TF-IDF weighting scheme. The modified node weighting function then looks as follows:

$$Node\_weight(i) = D_{C(i)} + SC(i) + Neigh_{Imp}(i) + F(i) + L(i) + \left(TF(i) \cdot \text{IDF(i)}\right)$$

All these modifications slightly improved the results as our evaluation demonstrates. The best modification proves to be *KECNW_use_tfidf.* However, the quality gain is only in the range 0.05 around the F1 score results of the TF-IDF keyword extraction approach.

Ranking of the keyword candidates

The original approach of candidate scoring uses the sum of all scores of the individual terms belonging to a keyword candidate. Note, multiple words can form a longer sequence for a keyword candidate. However, this approach favours much longer candidates because the sum gets larger with more words in a candidate sequence. This is undesirable and alternatively, we used the average of the individual terms instead of the sum. As confirmed by our evaluation, this method achieves better results and is therefore used in our implementations.

Evaluation

The evaluation measures for these approaches are precision, recall and the F1 score. The keywords are tested with the specified keyword dataset from the Web of Science.

We evaluated scores for increasing numbers *n* of most relevant keywords detected by the algorithms. The results are shown in Table 1, Table 2 and Table 3. Since most authors assign multi-term keywords, each automatically extracted keyword that is present in the authors keywords only partially is counted as a hit. It is noticeable that the TF-IDF, Log-Likelihood and KECNW are very close to each other. Only RAKE/TAKE (RaTa) is far behind in comparison.

To test the average scores for multi-word keywords we extracted the candidates with the TAKE methodology (RAKE candidates were found to be not optimal). The evaluation is presented in Table 4, Table 5 and Table 6 and demonstrates that the quality of the scoring approaches is similar to the single word extraction evaluation, but a candidate only counts as a hit if the extracted keyword is completely matching an author's keyword. We used the variant *KECNW_use_idf* for testing the KECNW algorithm, since it turned out it slightly improves the results.

Subject area classification

To create and evaluate the classifiers, each dataset for the Web of Science and GEPRIS classification is divided into a training (90%) and a test set (10 %). All publication and project abstracts are pre-processed. This includes lemmatization for English texts and stemming for German ones because a simple lemmatization for German texts was not available in our processing software. We extracted both, unigrams and bigrams, in order to keep a textual context in the feature set for the classifier. We used LIBLINEAR as SVM implementation (Fan, Chang, Hsieh, Wang, & Lin, 2008). Since the examples can have multiple labels, the problem was transformed to binary relevance classification. Thus, the SVM creates a separate classifier for each label, which only specifies for this label whether it applies to a given document or not. Furthermore, we extended the classification scheme to classifier chains which use the results of the previous classifications for each classifier to take label relationships into account (Read et al., 2011). Classifier Chains (CC) are an extension of the binary relevance method and integrate label relationships into the calculation of classifiers. Both use one model per label for classification. In CC, this is used to form a chain of models. The basic structure of the input vector remains the same, but starting with the second model in the chain, the previous labels are appended to the feature vector. Ensemble of Classifier Chains (ECC) solve the problem of order. To ensure that results do not depend on the order of the classifiers, a constant number of CC classifiers with randomly selected sequences are calculated. Our ensembles of classifier chains use a total of 11 iterations with randomly selected orders of classifiers. In addition, we tested whether it makes sense to change the threshold value for setting the labels. The original method calculates a threshold value by using the mean value of the estimates (either 0 or 1) for each classifier of the same label (Method A). For example, when looking at 11 iterations representing 6 predictions indicating 1 and the remaining 5 predictions indicating 0, the threshold should be less than 6/11. Another proposed approach uses the probability of a classifier that the label should be set (between 0 and 1) instead of the exact estimate (Method B). The latter methodology can considerably improve the results as shown in Table 7 and therefore a threshold value based on probabilities was used for all further evaluations.

Table 7: Comparison of using the traditional and altered threshold calculation scheme while employing ECC.

		0/1 Loss	*Hamming Loss*	*Accuracy*	*F1 Score*
Method A	GEPRIS 1	0.096	0.045	0.911	0.913
	GEPRIS 2	0.279	0.035	0.754	0.766
	GEPRIS 3	0.423	0.02	0.591	0.597
Method B	GEPRIS 1	0.097	0.044	0.912	0.915
	GEPRIS 2	0.233	0.027	0.813	0.828
	GEPRIS 3	0.539	0.033	0.619	0.686

In addition, the influence of using over- and undersampling were examined in the case of the Web of Science categories. Oversampling replicates the examples of the minority class until the minority and the majority class have the same size. Undersampling deletes random examples of the majority class until the minority and majority class have the same size. Our evaluation, as shown in Table 8, revealed that oversampling is more suitable for our purposes than undersampling with different tested ratios. Note, the quality differences between Table 7 and Table 8 are due to the different datasets. We simply demonstrate the impact of threshold selection and over- and undersampling. We present the final scores in the next section.

Table 8: Comparison of using Oversampling and Undersampling with different ratios (Minority:Majority) while employing ECC. Note, the Web of Science dataset was used for this evaluation.

	0/1 Loss	*Hamming Loss*	*Accuracy*	*F1 Score*
Undersampling 1:1	0.788	0.007	0.269	0.292
Undersampling 1:2	0.786	0.007	0.271	0.289
Oversampling 1:1	0.79	0.008	0.367	0.431

Evaluation

We applied evaluation measures as presented by Read et al (2011) for multilabel classification and the corresponding results are shown in Table 9. The experiments with ECC instead of single classifiers significantly increased the quality depending on the number of different labels. The higher the number of different labels, the more the quality improved. Therefore, all classifiers for the evaluation on Table 9 used ECC. In some examples of the test dataset it may happen that the all probabilities for assigning a label are below the required threshold. In such cases the label with the highest probability is selected for these examples. As expected, the classification quality decreases if more different labels are classified. Nevertheless, the results are sufficiently good and suitable to be used. We also observed misclassified categories, which are nonetheless often semantically similar to the correct labels.

Table 9: Evaluation scores for classification with SVM based on two different datasets and different amounts of categories. The number of categories is noted in brackets.

	GEPRIS			*Web of Science*	
	First Level (4)	*Second Level (14)*	*Third Level (48)*	*Normal (254)*	*CWTS (5)*
0 / 1 Loss	0.097	0.233	0.539	0.7	0.216
Hamming Loss	0.044	0.027	0.033	0.008	0.055
Accuracy	0.912	0.813	0.619	0.473	0.871
F1 Score	0.915	0.828	0.686	0.534	0.9

Application in Search Index

We applied our approach for keyword and category extraction on a sample of 4362 unlabelled and unprocessed publications from the Research Report of Leipzig University as described in the Datasets. Of these, we inserted the publication title, abstract, publication year and the first mentioned author into a Solr full-text index. Additionally, we automatically annotated the Web of Science categories, research areas, CWTS Leiden categories and the top 10 keywords per document using our proposed methods. The categories were extracted using ECC and the keywords were determined by using KECNW with the TAKE candidates to represent multi-term keywords. The categories were extracted using ECC and the keywords were determined by using KECNW with the TAKE candidates to represent multi-term keywords.

We illustrate the application in a search index with English examples. The usage examples of the generated metadata are divided into two areas:

1. Expansion of conventional search queries using pseudo relevance feedback (Xu & Croft, 1996)
2. Facetted search queries on metadata for analysis purposes

A conventional search query refers to a search within the title and abstracts of the texts with one or more search terms defined by the user. In the full-text index, we defined the individual components such as title and abstract as searchable fields in tokenized form. The query is built with a logical disjunction. Since we assume that a search result has a higher relevance if the search term appears in the title and not only in the abstract, we weighted the search differently. Boosting is used to append a multiplier to single search fields or search terms. We use this mechanism in order to calculate the relevance score.[6] The search query is expanded by using the results of the conventional search query. We acquire the keywords and Web of Science categories from each of the search results and reintegrate them into the search query.[7] For example, we find 33 documents when searching for the term *cardiology* within titles and abstracts. From these the keywords and the categories are extracted, which are used to expand the conventional search with logical disjunctions. In this example, a keyword or a category must appear more than twice in the result set to be embedded into the expanded search query. In addition, we define a boosting factor to each field. It is assumed that search terms, which are included in the title or the abstract of the documents, give more relevance to them. The keywords are also more important for the search than the categories and therefore have a higher boosting factor. The boosting factors are intuitively set as following:

- Title ^4
- Abstract ^2
- Tokenized Keywords ^1
- Untokenized Keywords ^1.5
- Categories ^0.5

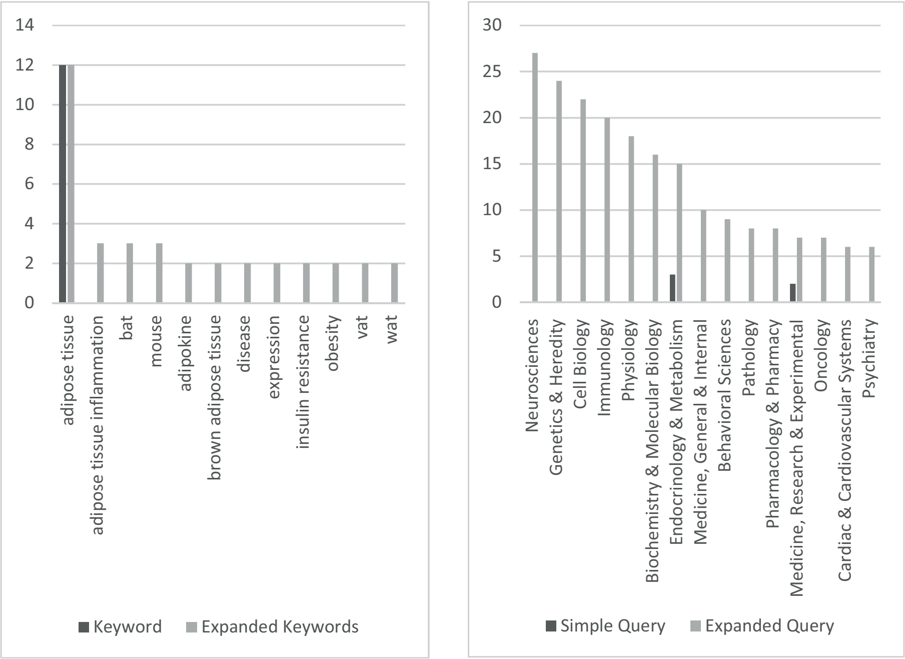
Figure 1 shows how the search query can be expanded directly on a keyword search in the title and abstract. The simple search finds only two categories occurring in documents which contain the query terms. But the documents containing the term *adipose tissue* also deliver 11 further keywords, which co-occur at least in 2 documents from the search result. These keywords expand the search query and we obtain a larger result set. Additional categories (which occur six times or more) can be found that are relevant to the enriched keywords. In this way we are

[6] https://lucene.apache.org/solr/guide/6_6/the-dismax-query-parser.html

[7] Added keywords (>2): patient, cardiology, tavr, catheter ablation, dcb, ehra, esc area, esc member country, geographical esc region, lesion revascularization, non-european esc country, predictor, pulmonary hypertension, revascularization

Added categories (> 2): Cardiac & Cardiovascular Systems, Health Care Sciences & Services, Medicine, General & Internal, Peripheral Vascular Disease, Surgery able to obtain a profile which allows us to investigate the research activities of Leipzig University relevant to the topic reflected by the original search term.

Figure 1: Histograms of collected keyword and category information well suited for profiling of academic careers, faculties or research projects.



Discussion

In this work, we presented and evaluated several known algorithms for keyword extraction and text classification in scientific publications and project descriptions. In an example, we augmented the documents in a full-text index with the results of these algorithms to support the search process and to enable analysis applications based on the document repository, such as profiling authors or faculties. The evaluation demonstrates that graph-based keyword extraction approaches such as KECNW can compete with TF-IDF based algorithms with respect to precision, recall and F1 Score. However, the computing time, which is considerably longer than that of TF-IDF based approaches, has been noticed negatively. This can possibly be improved but was not pursued in this work. Furthermore, the candidates of TAKE gave better results than those of RAKE. We also found out that the score calculation of the candidates with average values achieved better results than with summation, since the average prevents the preference of longer keywords. Nevertheless, the individual term scoring of RAKE / TAKE was not able to keep up with the results of the other presented methods.

Keyword extraction methods that only set a single term as a keyword are not meaningful enough since authors frequently assign multi-term keywords. The candidates extracted by TAKE have greater accordance with the author keywords than those extracted by RAKE. However, many keywords that are not directly contained in the text are missing since the authors derive them from the text with the help of their own knowledge. However, since authors also assign keywords that do not appear directly in the text, a fixed vocabulary is required that can be assigned to texts. One such approach is Wikify (Mihalcea & Csomai, 2007). Wikify uses the Wikipedia headings as a fixed vocabulary and assigns them to the texts. As an additional

improvement, one could create a stopword list given a specific context such as publications and project descriptions. This can prevent unimportant terms from becoming too important, such as the word *project* in project descriptions, which usually describes all these texts.
To classify the texts, the Web of Science categories with the derivable CWTS Leiden categories where used as a taxonomy for English publications. For the German project descriptions, our experiments used the first three levels of the GEPRIS classifications as taxonomies. We applied a SVM in order to classify the documents. Since the texts of these domains cannot necessarily be assigned to a single label, we transferred the problem to binary relevance and created a single classifier for each label. Due to the resulting class imbalance, it is inevitable to use oversampling as the evaluation demonstrated. Furthermore, we implemented ensembles of classifier chains in order to include label hierarchies. This is particularly profitable with a great number of different labels. The classifications results are satisfactory. Only the Web of Science categories appear to be problematic with regard to their low F1 score. Due to the large amount of different labels, which may overlap thematically or could also be superordinate fields, it is difficult to determine an exact result. With the test data, it often happens that labels are awarded that do not match the correct label but are very close to it and one would think as an assessor that the label was assigned correctly. Another way to improve the classification is to create larger training datasets. Especially in the Web of Science dataset with 254 classes it is difficult to create a good classifier with only ~200 examples per label. Finally, it would be possible to use PU Learning (Sansone, De Natale, & Zhou, 2018). PU means *positive unlabeled*. Although there are labels for all examples in the training and test datasets, it may be useful to consider the false class as unlabeled, because some examples from the false class may overlap with the labels of the positive class. For example, there are publications in the Web of Science that are only assigned to the class *Cell Biology*. However, there is also the class *Biology*, which is theoretically a superordinate field of cell biology. Since this is a class, which can be described with the same features as *Cell Biology*, it does not make any sense to train such a document as negative class example. PU Learning would consider this aspect.
Finally, we demonstrated the application of the extracted metadata in the context of search indexes and profiling. A search query expansion creates results that are additionally relevant for a search query. Furthermore, we can create categorical summaries of documents thanks to the metadata determined. The extracted metadata enables researchers to use keywords for finding other researchers working on the same topic. This aspect could promote cooperation between researchers who might not be aware of mutual research interests.

The social sciences and their publishers: Publication, reception and changing meaning of German monographs

Christoph Thiedig

German Centre for Higher Education Research and Science Studies, Schützenstr. 6a, D-10117 Berlin (Germany)

Abstract

Books are an important part of scholarly communication in the social sciences and humanities (SSH). A number of developments affecting both the SSH and their publishers seem to have shifted the relative importance and prestige of the various publication types in favour of the English journal article and to the detriment of books. While these developments have been studied quite extensively in other countries, empirical analyses of German SSH publishing are still rare. This paper attempts to narrow this gap by investigating publication and citation patterns of German social science monographs since the 1980s against the backdrop of changes in SSH communication and publishing. Using a comprehensive bibliographic dataset for the social sciences in Germany and corresponding citation data, it addresses the question of the relevance of scholarly monographs today.

Introduction

Publication practices in the Social Sciences and Humanities (SSH) are characterized by a pluralism of publication types. Monographs, edited volumes and articles in peer-reviewed and not peer-reviewed journals are common ways of publication. In addition, various other types of publication are produced as well, among them reports, reviews, *Festschriften*, or articles for the lay public. A lot of this communication takes place on a national level (Hicks, 2013; Nederhof, 2006). National language publishing is, thus, much more common in the SSH than in other scientific disciplines, where communication predominantly takes place in English peer-reviewed journals with international scope.
In the social sciences, books and articles are of similar importance (Hicks, 2004). However, they exhibit different characteristics e.g. with regard to the acquisition process (Powell, 1985), author characteristics (Puuska, 2010), content and methodology (Münch, 2011; Swygart-Hobaugh, 2004), and the work's reception (Hargens, 1991; Sullivan, 1994; see also Clemens et al., 1995). These characteristics attest to different publication and reception contexts which influence the creation and dissemination of knowledge in the SSH. In the following chapters, I briefly outline three developments that have seemingly shaped SSH communication considerably – the increasing use of bibliometric indicators in research evaluation practices, changes in library acquisition behaviour connected to the 'serial crisis', and corresponding developments in the field of academic publishing. I argue that these developments have shifted the relative importance and prestige of the various publication types in favour of the English journal article and to the detriment of books. I will then describe the data and methods used to empirically assess the state of monograph publication and reception in German SSH and present first analyses. A final chapter discusses the results and provides a conclusion.

Evaluation of research output

The first development concerns the use of bibliometric indicators which now routinely inform research evaluation measures (Hicks, 2012; Moed, Glänzel & Schmoch, 2004; Rijcke et al., 2016). Criticism of such evaluation practices concerns e.g. the selective coverage of SSH publications in the relevant databases deemed unrepresentative of actual publication practices (Gläser, 2006; Hicks, 2004; Nederhof, 2006) and the appearance of objectivity suggested by broadly available bibliometric indices (Weingart, 2005), leading to rash use of indicators in some disciplines despite heterogeneous citation practices and motives, small sample sizes and an insufficiently developed theory of citation (Bornmann & Daniel, 2008; Moed, 2005). Such

reactive evaluation measures might create incentive structures in which the increase of the entities measured becomes an end in itself (Bornmann, 2011; Espeland & Sauder, 2007).
Bibliometric indicator use in evaluation and allocation procedures has raised the importance of the English journal article. Butler (2003) observes an increase in SCI-indexed article publications after the introduction of a publication-based component in Australian funding allocation. For Norwegian universities, Kyvik (2003) shows a substantial gain in importance of English journal articles between 1980 and 2000, especially in the social sciences. Recently, Kulczycki et al. (2017) find an increase in the number of journal articles and English language publications in Poland between 2009 and 2014, which they attribute to changes in science policy incentive structures. For Germany, Münch (2011) warns of unjustified prominence of the English journal article and the devaluation of books and other publication types.

The 'serial crisis'

Changes in scholarly communication also affected the academic libraries and publishers. Since the 1980s, increases in journal subscription costs (Kyrillidou, 2006; Thompson, 2005; European Commission, 2006) exacerbated by consolidation in the field have put strains on libraries' stagnating budgets. The self-reinforcing cycle of shrinking subscription numbers and price increases for journal bundles commonly known as the 'serial crisis' has furthered this development. Digital infrastructure has additionally bound increasing parts of libraries' budgets. As a result, monograph acquisition stagnated or decreased (Thompson, 2005; for Germany, see Kopp, 2000; Kirchgäßner, 2008).

Developments in the publishing field

In the field of academic publishers, especially in STEM publishing, mergers and acquisitions have led to oligopolistic structures (Larivière et al., 2015). Another central development is the observable decline of scholarly monograph publishing since the 1970s (Thompson, 2005). Cost reduction, price increases, a larger title output or the exploration of new (mass) markets have been some of the coping strategies employed by publishers (ibid.).
Compared to Anglo-Saxon developments, the German publishing landscape is still shaped by a heterogeneous arrangement of small and mid-size publishers, especially in SSH publishing (von Lucius, 2005). Since the 1990s, an increase in managerial-led publishing houses and the concentration of resources as a result of mergers and acquisitions can be observed (ibid.).
For sociology publishing in Germany, Volkmann et al. (2014) observe the emergence of a fast-growing market leader able to significantly advance digital dissemination of scholarly literature via its online platform and thus shape researcher's reception practices, bearing the risk of rendering smaller publishers increasingly invisible. Library budget restrains are felt here as well, leading to lower print-runs for monographs and edited volumes. Tendencies of internationalization, on the other hand, are not very pronounced (Volkmann, 2014).

Changes in scholarly monograph publishing

The developments sketched above suggest that monograph publication becomes increasingly less attractive for both SSH researchers and publishers alike. While they provide only a partial view, they indicate significant changes in scholarly communication bearing further study. An important strand of research on this matter concerns changes in scholarly communication patterns. Despite efforts to increase coverage in databases such as Scopus or the Web of Science Core Collection (Glänzel, Thijs, & Chi, 2016), bibliometric analyses comprising books and book chapters are still dependent on national bibliographic databases.
Empirical analyses of (national) scholarly book publishing seem to accrue in recent years: Engels et al. (2018) use data from five comprehensive coverage national publication databases in order to analyze shares of monographs and book chapters among peer reviewed SSH

publications between 2004 and 2015. They observe stable shares of monographs for most of the countries studied, but a seeming decline in the share of social science monographs in Finland, Norway, and Poland. Similarly, Kulczycki et al. (2018) analyze all SSH publications from eight European countries for the period of 2011-2014. They find differing publication patterns across fields and countries, with stable publication patterns for some, but significant changes in other countries (notably Poland and the Czech Republic) relating especially to the share of monographs, which they attribute to changes in science policy and evaluation methodology respectively (for monograph publishing in Poland, see also Kulczycki, 2018). In all countries, a growth of English language publications could be observed.

Empirical analyses of German language SSH publication practices are rare, since Germany currently does not have a national SSH bibliographic database (Sīle et al., 2018). This paper attempts to narrow this gap by investigating publication and citation patterns of German language social science monographs since the 1980s. Based on the developments sketched above, I argue that the relative importance and prestige of the various publication types has shifted in favour of the English journal article and to the detriment of books. Thus, I broadly expect German-language SSH monographs to be published less frequently over time, in smaller circulation, and to be cited less frequently over time.

Data and methods

The analyses presented here are based on the Social Science Literature Information System (SOLIS) bibliographic dataset provided by GESIS – Leibniz Institute for the Social Sciences. An information service on German Social Science literature, SOLIS collected bibliographic data on articles, edited volumes and their chapters, monographs, and grey literature from sociology, political science and other social science disciplines. As the SOLIS service has been terminated, GESIS now provides the database as a dump.[i] Containing more than 478,000 entries, it covers the ‘core’ of German language sociology literature (Bärisch et al., 2008) and thus represents a unique dataset for the analyses of German language social science publication practices over time.

In order to account for changes in the reception of scholarly monographs, SOLIS entries were matched with Scopus citation data via DOI (89,908 references matched to 901 DOIs). The references’ publication types (“Book”, “Chapter/contribution”, journal article, and Other) were approximated based on the structure of the Scopus data. For “book” references, the language was determined as well. Despite its Anglo-Saxon bias (mostly English-language SOLIS publications had matching DOIs), this sample allows for comprehensive citation analyses on the basis of a curated bibliographic dataset.

In addition, reference patterns of articles in four prominent German-language sociology journals[ii] are studied. Using Web of Science citation data, 317 ‘articles’ containing 16,165 references were analyzed, covering all available data of the 1985, 1995, 2005, and 2015 volumes. Publication type and language were assigned to all references via manual coding.

Results

Fig. 1 presents the shares of German-language SOLIS publications over time. Since chapters in edited volumes are insufficiently captured in SOLIS, they have been excluded from the analyses. Neither journal articles nor monographs exhibit particularly strong trends.[iii] Overall, the share of monographs in the dataset slightly increases; a decline of scholarly monographs as measured by publication output can thus not be observed here.[iv]

The reference patterns of SOLIS publications in Fig. 2 show an increase in the citation of journal articles (and a reduction of citations to “books”) in the period of 2000-2004, with similar reference shares in the following years. This trend can be observed for both journal articles and monographs (not differentiated here). While these results suggest relatively stable citation practices, Fig. 3 indicates an overall increase in the median age of cited “books” and journal articles respectively. This trend is especially pronounced for monographs.

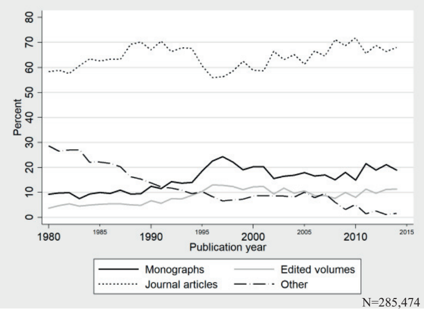

Fig. 1: Share of publications, 1980-2014

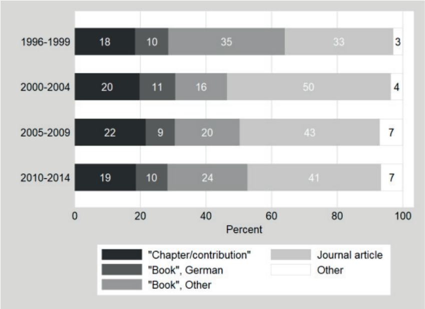

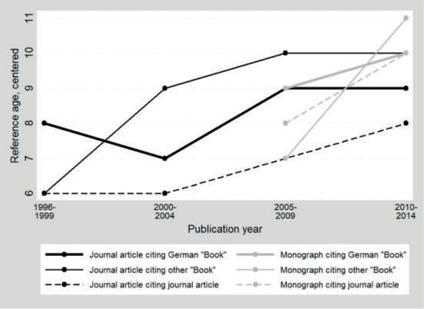

Fig. 2. Share of references by publication type   Fig. 3. Median reference age by publication type

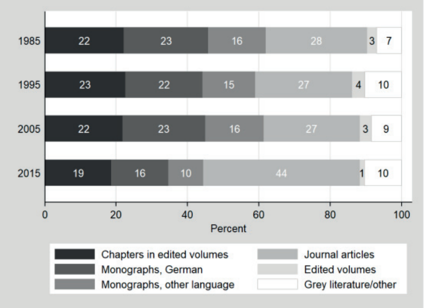
The reference patterns of the four sociology journals in Fig. 4 show similar findings. While the share of German-language monographs is expectedly higher than in the SOLIS sample, the most recent volume shows a distinct change in citation pattern closely resembling its SOLIS counterpart: journal articles are cited more often than before, and monographs less. Analyses of the references’ median age (Fig. 5) show that, while there is an overall increase in median citation age across all publication types, both German and other books ‚age‘ the most.



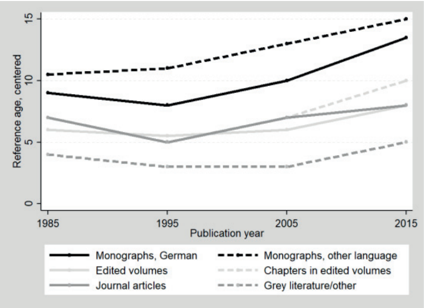


Fig. 4. Share of references by publication type   Fig. 5. Median reference age by publication type

Discussion and conclusion

The analyses of SSH communication patterns has received increasing attention in recent years and has highlighted the importance of national bibliographic databases as comprehensive data sources for such endeavors. Due to the lack of a national database, analyses of German SSH publication practices remain rare. This paper attempts to narrow this gap by investigating publication and citation patterns of German language monographs using a comprehensive bibliographic dataset for the social sciences. Regarding the question of the relevance of social science monographs today, the results are mixed. Publication output might e.g. not necessarily be an indicator of continuous relevance, since publishing more titles is a common strategy to balance smaller circulation. In addition, differences in editorial processes, both between book and journal publication as well as over time, might account for some discrepancies between reference age. Further analyses, both quantitively and qualitatively, will be needed in order to qualify these findings more thoroughly. The present study intends to provide an impetus for this as well as the further assessment and interpretation of (inter)national SSH publishing.

Sorting out Guidelines for the Good Evaluation of Research Practices

Abstract

In this paper, we propose the adoption of moral philosophy and in particular normative ethics, to clarify the concept of "good" evaluation of "research practices". Our perspective is based on the idea that research is a form of social practice according to MacIntyre (1985)'s conceptualization. From MacIntyre's notion, we elaborate three typologies of researcher: the *leader*, the *good* researcher and the *honest* researcher. Reflecting on what is a "good" research practice and on what is the role of researchers in it provides insight into some aspects of both the self-assessment process and how this promotes individual improvement. Moreover, this kind of reflection helps us to describe the functions (missions) of the research practices. A "good" evaluation should take into account all the building constituents of a "good" research practice and should be able to discriminate between good and bad research practices, while enforcing the functions of good research practices. These reflections may be the starting point for a *paradigm shift* in the evaluation of research practices which replaces an evaluation centred on *products* with an evaluation focused on the *functions* of these practices.

Introduction and main objectives

In this paper, we propose to use some of the notions employed by contemporary normative ethics to develop a framework for the "good" evaluation of research practices. We define *ethics* as the sphere of our reflection, language, emotions and behaviour that concerns "good" life, where "good" indicates what favours human flourishing in the various social practices in which human life is expressed. Following the extensive literature on the subject, we define *normative ethics* as that part of moral philosophy that formulates and justifies principles of conduct and concepts that are conceptually connected to the moral good. Basic ethical principles and concepts govern our self in two ways. They help us (i) to make the right sorts of decisions (*practicality requirement*), and (ii) to form a correct evaluation of other's behaviour (*evaluative requirement*).

Usually, normative ethics (see e.g. Furner, 2014) is not considered by evaluative bibliometrics and research evaluations. The consequence of this deficiency is that although there is a proliferation of increasingly sophisticated quantitative methods to evaluate research (see for example the case of university rankings), there is still a lack of clarity on how to understand and operationalize the notion of "good" evaluation of research practice. One of the reasons for this is the lack of a framework for the assessment of research and its impacts (Daraio, 2017). We believe, however, that the concept of "good" is a crucial standard against which to evaluate research practices enabling us to assess them in light of broad human interests.

The characterization of the notion of "good evaluation" of research practices requires the description of "good research practices". This is because a good evaluation takes into account the constitutive elements of a good research practice. Our proposal is to start from a general notion of a "good social practice". From this notion, we specify the notion of "good research practice" and from the latter we specify that of "good evaluation" of research practice. This involves different moves that can be schematically indicated in three points.

- First, clarifying the notion of "social practice" explaining what it means to comply with its rules, and which elements of our *psychology* can account for its emergence. As it will become clear later on, to comply with social practices requires agents to develop specific traits of character which unable agents to grasp, produce and further the "internal goods" of the practices they join. These traits identify those who excel in following the practice. They are *exemplary* figures that the other participants in the practice want to emulate.

- Second, examining how the practice affects the life of those who inhabit it.
- Finally, setting the standards in the light of which assessing the overall effects of practices on society as a whole.

To undertake these tasks, we propose to use different resources offered by philosophical reflection on morals. In particular, we use tools borrowed from utilitarianism, virtue ethics and McIntyre (1985)'s characterization of social practice. Following this track, the paper aims to fill a significant methodological gap in the field of the evaluation of research. We argue that the evaluation of research activities, including research projects and programs, together with their outcomes, should not be limited to assess the products or quantitative aspects of the production and dissemination of recorded information, but should also take into account the *psychology* of the actors involved in this process (authors, readers, etc.), including their motivations.

Taking character qualities as essential inputs within the process of generating research outputs is not a completely new idea. Robert Merton (1973) famously illustrated the link between traits such courage, self-confidence, resilience, taste and the recognition from one's peers along with the capacity to produce excellent quality research. The way we use psychology, however, diverge in at least two ways from Merton's.

First, he uses individual qualities to explain and justify differences in capacity to acquire outstanding achievements between future Nobel laureates and average researchers. We instead use virtues to understand the difference between the activity of researchers, whose motivations cannot be described independently of the *intrinsic* (non-instrumental) desire to acquire the "internal goods" of the practice - e.g. the peculiar pleasure of undertaking new line of research, excellence in analytical skills, a particular taste for problem raising, etc. -, and those who participate in the research practice mainly out of desire to acquire goods *external* to the practice, e.g. power and wealth.

Second, unlike Merton, who merely mentions the excellences in character, we want to present a characterization of these virtuous psychological traits that highlights their constitutive role in producing a "good" research practice. We argue that a "good" practice is characterized, among other things, by the fact that its participants have an *intrinsic* (non-instrumental) interest in seeking the "internal goods" of the practice together with the capacity to grasp and appreciate them. In line with McIntyre's approach we shall argue that the possibility of achieving these "goods" depends on whether participants in the practices have, cultivate and teach others certain virtuous character traits. In the following, we will provide a detailed description of what "internal" and "external" goods of the practice are.

Our conceptual framework

Our perspective is based on a highly plausible hypothesis: the idea that a good scientific/academic research is a form of social practice *a la* MacIntyre. Following MacIntyre's formulation of a social practice (MacIntyre 1981 first ed.; 1985: 187; Vaccari 2012) we define a *good practice* as "any coherent and complex form of socially established cooperative human activity through which goods internal to that form of activity are realized in the course of trying to achieve those standards of excellence which are appropriate to, and partially definitive of, that form of activity, with the result that human powers to achieve excellence, and human conceptions of the ends and goods involved, are systematically extended" (MacIntyre, 1981 first ed.; 1985: 187).

That scientific/academic research can be described according to the McIntyre model is strongly justified by the well-known definition of research practices offered in the Frascati Manual. According to this document (OECD, 2015, p. 44) Research and experimental development (R&D) "comprises creative and systematic work undertaken in order to increase the stock of knowledge - including knowledge of humankind, culture and society- and to devise new applications of available knowledge". For an activity to be an R&D activity, it must satisfy five core criteria. The activity must be: 1. Novel, 2. Creative, 3. Uncertain, 4. Systematic, 5. Transferable and/or reproducible.

On the basis of this definition, we characterize a *good research practice* as any coherent and complex form of socially established cooperative human activity through which its participants, through the exercise of a set of refined human psychological qualities or virtues (called "human powers" or virtues by MacIntyre), contribute to the advancement of the body of knowledge that is constitutive of that practice. The term "good" is used to identify a refined and reason-mediated use of typically human abilities (e.g. empathy, imagination, courage, self-reliance, the ability to bind oneself to rules perceived as authoritative, etc.) that yields a meaningful and fulfilling life.

From MacIntyre's notion of research practice we elaborate three typology of researchers: the *leader*, the *good researcher* and the *honest researcher*.

The *good researcher* is a typical participant of a good research practice defined so far – she/he participates in the practice learning and developing the virtues of the practice. The *good* researcher employs typically human qualities to respond in the best way she/he can to the problems that are typical of that practice enabling her/him to creatively advance a particular stock of knowledge. From the good researcher we distinguish the *leader researcher* and the *honest* researcher. The *leader researcher* is one who achieves an outstanding level in the development of creative and social virtues enabling her/him to produce excellent outputs and to be a motivating leader in research group. Finally, the *honest researcher* is the one who does not produce outputs that are contrary to good research practices. More precisely, the honest researcher typically exemplifies the researcher who has completed her/his PhD and is at the beginning of her carrier. Within research institutions, this figure mainly carries out her/his activity in the service of more experienced researchers. Within the university, she/he carries out her teaching activity mainly as a tutor not having yet her/his institutional course during one of the terms. The figure of the honest researcher generally progresses towards that of a good researcher and, in some cases, becomes a leader. However, this may not be the case. In such a situation, an honest researcher is one who, despite having a permanent job as a lecturer or researcher for many years, continues to carry out the tasks she/he was carrying out at the beginning of her career. She/he, however, grasps the research practice in which is involved, with its "internal goods", and fulfils his/her role of being at the service of the practice.

A *good evaluation* of research practices is then an evaluation that is able to take into account the different elements that characterize a good practice, that is, both its outcomes (which can be classified in *internal* and *external goods*, following MacIntyre) as well as the virtues of these three types of researchers.

We characterize *internal goods* as both the outcomes of research and the subjective experiences related to participation in the practice of research, which does not necessarily translate into outputs. We call *external goods* the positive and measurable effects of research results or outcomes on society as a whole.

We argue that good evaluation must therefore be able to distinguish good practice from bad practice. The first is that in which researchers participate in the practice because they are motivated by both internal and external goods. A bad practice, on the other hand, is one in which participants are in no way motivated by the intrinsic desire to achieve internal goods but only act out of the desire of goods external to the practice.

To carry out a good evaluation it is not sufficient to follow abstract and impartial rules, but it is also necessary to have developed *certain virtues* that enable the evaluator both to apply those rules when they conflict with their partial interests and to interpret them in such a way as to make them applicable to the specific case.

We propose to identify the most significant virtues of the *good* evaluator with justice, empathy and practical wisdom. We will analyse them in details in the following.

***Internal* "goods" and *external* "goods" of a research practice *à la* MacIntyre and Nussbaum's theory of abilities**

Let us now examine in detail the nature of external and internal goods as well as how this distinction affects the plurality of standards that constitute good evaluation practice.

Since its products are both internal and external to scientific practice, having an impact outside the research community that potentially affects the well-being of society as a whole, it is advisable to use different styles of evaluation to assess each of them. Therefore, in addition to MacIntyre's concepts of virtue ethics, our framework will also use notions from Nussbaum (2006)'s theory of abilities, and from utilitarianism (as discussed in the next section).

We believe that nowadays research practices require hybrid forms of combination between internal and external goods. Different factors can explain this transformation, including the changes in the way in which science is produced and interacts with society (Scott, 2003).

The model of the virtues can be useful to identify those dispositions that unable researchers to grasp and respond to, in a good enough way (Swanton 2003:1), the internal and external goods of the research practice. As we will show in a moment, these goods include objects, and ways of socially interact with persons and educate them.

To better characterize the notion of social practice that we are using to describe scientific research, it is useful to articulate further the distinction put forward by MacIntyre between "internal" and "external goods".

"Internal goods" to a practice are high quality *outcomes* of the practice that (a) can only be specified in terms of some specific practice, as for example the way of conducting an empirical experiment; the practice of university teaching through lessons, seminars, individual tutoring activities; the practice of interpretation and problematization of the text of classical authors in the humanities; etc. and (b) can only be identified and recognized by the experience of participating in the practice in question. Those who lack the relevant experience are incompetent thereby as judges of internal goods (MacIntyre 1985: 189). Internal goods are reachable by those participants in the practice who practice it as an end in itself and not merely as a means to get something else, e.g. money, power, prestige. According to MacIntyre, these goods include three kinds of *outcomes*. They are

- *the high quality in performance* (e.g. ability to question a text; ability to ask relevant questions during an experiment; ability to motivate one's own research group or students in class, etc.);

- *the high quality of the outcome itself* (e.g. articles, books, research projects, discoveries, etc.);

- *the great value that comes from living a certain kind of life* – the fact that occupying a certain professional role in a research practice contributes to the unity and value of the researcher's life.

The last point needs more articulation. The idea is that those who participate in a practice by acquiring its internal goods are likely to consider it as *something that makes their lives meaningful*. They will tend to describe their lives as those of the participants in a certain practice and this will give a unitary character to the different parts of their biography.

Unlike internal goods, external ones are only "externally and contingently attached" to the practice by the accidents of social circumstance and typically includes prestige, status and money. There are always alternative ways for achieving such goods, and their achievement is never to be had "only" by engaging in some particular kind of practice (MacIntyre, 1985: 201). Moreover, external goods, when achieved, they are always some individual's property – i.e. the more someone has of them, the less there is for other people. They are characteristically objects of competition in which there must be losers as well as winners. On the contrary, internal goods include the outcome of competition to excel, but also positive externalities. This means that their achievement is a good for the whole community who participate in the practice (e.g. Bowlby's attachment theory has transformed the way of seeing the relationship between mother and child by reducing trauma in hospitalized young children; Moore's naturalistic fallacy argument has helped expose many fallacious arguments in philosophical reflection).

The evaluation of the particular practice covered by this paper requires that both internal and external goods are taken into account. On the one hand, it is necessary to assess whether the practice of the academic/scientific research under examination is actually a good practice. In doing so, account must be taken of the excellence of its outputs, the way in which they are achieved (in accordance with the rules that constitute the practice), and the impact that following the practice has on researchers' life plans. On the other hand, we need to establish what consequences following the practice has on the values protected by the democratic constitutions in which the practices have taken hold. That is, we must assess whether the practices produce outputs that are in conflict with interests such as freedom, equality, health, respect for the environment, human dignity, and sociability.

In the light of this twofold requirement, we believe it may be helpful to interpret the two types of goods in the light of the capability approach developed by Nussbaum (Nussbaum, 2006). Specifically we holds the view that internal goods of the research practice are:

1. Use the senses, imagination and rationality in a typically human way, informed by adequate education. Be able to use imagination and thought in connection with our experience

and produce works that are the result of our autonomous and reflective choices (reinterpretation of Nussbaum's point 4: 95)

2. To be able to pursue the objectives of research without ulterior purposes but as intrinsic ends. Be able to have fun and play with activities related to the practice. Moreover, be able to acquire and use specific mental capacities connected with the exercise of the practice such as the ability to apply the rules of the practice to completely new and unexpected contexts, ability to grasp the saliences of the situation required to act in accordance to the practice, etc. (reinterpretation of Nussbaum's point 9: 95).

3. To be able to have attachments to people involved in the practice and to the outcome of research; to experience gratitude towards teachers and masters and justified anger towards those who betray our trust and violate our intellectual property. Be placed in conditions where one's potential and development is not hindered by fear and anxiety (reinterpretation of Nussbaum's point 5: 95).

Following the same approach, we argue that external goods are not only money, power or the reputation of the research institution and its capacity to attract investment, but also the impact research practice has on what Nussbaum has called the "human capacities necessary to live life worthy of human dignity". These capacities, should include:

1. *Life, Bodily Health.* Being able to live to the end of a human life of normal length – i.e. not dying prematurely, or before one's life is so reduced as to be not worth living – and being able to have good health, including reproductive health; to be adequately nourished (Nussbaum's point 1 and 2);

2. *Affiliation.* Being able to live with and toward others, to recognize and show concern for other human beings, to engage in various forms of social interaction; to be able to imagine the situation of another. Protecting this capability means protecting institutions that constitute and nourish such forms of affiliation, and also protecting the freedom of assembly and political speech. Having the social bases of self-respect and non humiliation; being able to be treated as a dignified being whose worth is equal to that of others. This entails provisions of non discrimination on the basis of race, sex, sexual orientation, ethnicity, caste, religion, national origin (Nussbaum's point 7: 96)

3. *Other Species.* Being able to live with concern for and in relation to animals, plants, and the world of nature (Nussbaum's point 8: 96)

4. *Control over One's Environment.* (a) *Political*. Being able to participate effectively in political choices that govern one's life; having the right of political participation, protections of free speech and association. (b) *Material.* Being able to hold property (both land and movable goods), and having property rights on an equal basis with others; having the right to seek employment on an equal basis with others; having the freedom from unwarranted search and seizure. In work, being able to work as a human being, exercising practical reason and entering into meaningful relationships of mutual recognition with other workers (Nussbaum's point 10: 96)

In order to take account of these goods, the evaluation of research practice must also be able to assess the ability of researchers to obtain them. To this end, the virtues of the participants in the practice should also be taken into account. Following once again the MacIntyre setting, we define virtue as "an acquired human quality the possession and exercise of which tends to enable us to achieve those goods which are internal to practices and the lack of which effectively prevents us from achieving any such goods (Macintyre, 1987: 191)".

A potential issue arising from taking this approach concerns the relationship between moral virtues and the virtues that are relative to those who practice scientific research. This is one aspect of the more general issue which concerns the possible tension between the traits of character that make us good as human beings and those that make us efficient as occupying a particular social role. For example, it may be argued that the ability to take a certain detachment from suffering may be a necessary trait in a physician who allows him to make crucial decisions by looking only at facts objectively without letting himself be clouded by emotions. This same trait, however, is not desirable within family relationships where the ability to participate in the emotional life of loved ones is a fundamental part of relational life. Likewise, although a professor's loyalty to his pupils can have the useful function of creating a close-knit group that works efficiently and does the good of research. This same trait could lead the teacher to misbehaviour when, in assigning a public job, he prefers one of his students to another clearly more competent one. These are, of course, simplifications, and one could argue that the more detailed the example becomes, the more so-called conflicts are mitigated. Mitigated as it may be, however, it could be argued that some dose of conflict between the virtues of participants in social practices and moral virtues exists. And if this is true, what is the point of arguing that philosophical ethics can help us define the virtues of the academic researcher?

Our thesis is that moral virtues can be interpreted in ways that allow a typically non-conflictual relationship with the role-specific virtues. According to our proposal, which follows the general lines of Swanton (2007)'s analysis, the relationship between virtues and role-specific ones runs in two directions. On the one hand, role-specific virtues allow moral virtues to be given content, which otherwise would be too vague and generic to offer a practical guide to action and to assessing the conduct of others. This is to say for example that the virtue of courage acquires its content only when it is grounded on the paradigmatic cases of courage that human beings find themselves living in their concrete social interactions as parents, friends, members of a community, etc. On the other hand, what virtue requires in different social circumstances is delimited by the general meaning of virtue. To return to the example of courage, what is required of a brave friend is partly defined and circumscribed by the fact that courage should not be confused with recklessness and disregard for danger.

Our proposal will make use of the following concepts. Following the analysis of Churchland (1998) and Swanton (2007) we define moral virtues as prototype virtues. These have a "high degree of generality, in which contexts such as the role of the agent, his relationship with others, social conventions, and the particular narratives of his/her life have been abstracted away" (Swanton 2007, p. 211).

The transition between the prototypes or moral virtues and the corresponding role specific virtue involves two stages:

1. The *thin* account gives the specification of the field of a virtue (its domain of concern) and states that the virtue is being well disposed in relation to that field. For example, *loyalty* is being well disposed with respect to 'sticking to' relevant individuals or institutions. *Trust* is being well disposed with respect to believing, supporting, and so forth relevant individuals.
2. The *thick* account is given by so-called 'mother's knees rules and basic accounts of relevant emotional and motivational dispositions (Hursthouse, 1999). These rules are characteristically unsophisticated and vague. These provides saliences and paths to assist the development of appropriate emotional and cognitive paths on the world. These different rules articulate the content of the prototype virtues so as to differentiate it according to the different social roles that the subject finds himself occupying.

The claim that prototype virtues are vague is central to the idea that *roles demands* do not characteristically conflict with those of being good as a human being. For example, insofar as honesty is a prototype virtue, it does mean something like *telling the truth* and not lying here and now. On the other hand, in the role-specific virtue of honesty for academics, the substantive question is *what counts as excellence* in the field of quoting, divulgating and disseminating information. *Only when more specific requirements are determined by role-differentiation do we know what it would be to act honestly as a human being.* However, given that honesty is a prototype virtue, an agent with that virtue will have emotional and cognitive dispositions which make his/her not ready to lie or distort the truth.

Given that prototype virtue are vague and need to be specified by role-differentiation, *how do they provide constraints to role virtue*? Our idea is that they provide anchors for moral reflections in role contexts, alerting us to possibilities of excess. Such anchors are traits of characters whose emotional and cognitive features are deeply rooted though early training.

Indeed, those treats of character can be introduced through the narrative of exemplar stories of leaders, may be included in training for young professors and so on.

Why we introduced this distinction? Because it may be useful to understand misconduct in the scientific practice.

In the conclusion of a recent report on Fostering Integrity in Research (2017, p.208-209) by the US National Academies, it is stated: “The committee reaffirms the central recommendation from Responsible Science [a previous report of 2002] that formally places the primary responsibility for acting to define and strengthen basic principles and practices for the responsible conduct of research on individual scientists and research institutions. At the same time, the committee based its recommendations on its understanding that the integrity of research depends on creating and maintaining a system and environment of research in which institutional arrangements, practices, policies, and incentive structures support responsible conduct. Fostering research integrity is an obligation shared not only by individual researchers but also by leaders and those involved with all organizations sponsoring, conducting, or disseminating research, including corporate and government research organizations.” Hence, the primary responsibility is on individual scientists. Fraud and misconduct have for several years been identified as a relevant problem of the scientific community. For a review, see Fanelli (2009). More recently, Fang et al. (2012) found that the main reason for retractions relies on misconduct.

Our conceptual framework allows us to distinguish (discriminate) good research practices from bad research practices.

The virtues a good research practice must have

We believe that a provisional list of these virtues should include:

a *Justice*: this virtue consists in the disposition, required above all by the professors and more generally by the evaluators of the performances and outputs of others, to treat others “in respect of merit and of the desert according to uniform and impersonal standard" (MacIntyre, cit., 191-192).

b *Resilience*: together with pride, this ability is indispensable to move forward in the search. It allows us to leave behind failures (paper rejected, unfunded projects, etc.) and to focus on future projects (Hormann, 2018).

c *Empathy*: In line with extensive literature, by this term we mean the human ability to feel the emotions and feelings of other people through a vicarious feeling that is similar to that of the person with whom we sympathize. We do not believe, however, that empathy in itself is a virtuous capacity in research practices. Since empathy is an instrument for reading the other's mind, it can also be used to manipulate others researchers in malicious ways. Empathy must be cultivated in such a way that it is rooted in the benevolent tendencies of human beings (Batson 2017: 2). In this way, empathy can allow the creation of a climate of *trust* between those who work within research institutions. Mutual trust is in fact an indispensable component in these practices given the fundamental fact of the asymmetry of power that characterizes those interactions (Baier, 1991).

d *Pride*: it is evaluative attitudes towards ourselves (Ardal 1966; Cohon 2008; Taylor 2015). Unlike other emotions, which simply motivate us to pursue or avoid objects, this traits of character fix our attention on persons, casting a positive or negative light on them. If I am proud of my child's success at school, my pride does not fix my attention on the 'merits of my child,' and still less on 'me in the role of father,' but on the whole of myself. As Cohon has rightly said, "when I feel pride, I am proud of something in particular [its cause] . . . But the attitude of pride is a pleasure or satisfaction not in that particular accomplishment or possession, but in myself in my entirety" (Cohon 2008: 166). We believe that the pride associated with one's own achievements in research and the consequent approval of one's peers or superiors is a fundamental spring that drives researchers to perform at best in their area of research (Tangney, 1999).

e *Humility*: the ability to accept the authority of the standards related to the rules that define the practice. I have to recognize that other participants know rules and know how to apply them better than I do. I have to be willing to learn from these people and accept their criticism (MacIntyre 1985: 193).

f *Patience:* or the ability to curb one's own immediate emotions, which could drive us to quickly complete a research in order to obtain as soon as possible the gratification of a positive result. To be able to wait and to be guided by a cautious scepticism that prompts us to control accurately the different steps of our investigation.

g *Practical wisdom*: it is a kind of super-virtue essential to make each virtue effective. It enables the virtuous agent to acknowledge and respond properly to the items in the field of the research practice, choosing the appropriate means for their own ends. (McDowell 1979).

Our thesis is that these virtues are those traits that permit to acquire the internal goods of research practices. We also argue that the link between virtue and internal goods is not instrumental but conceptual: internal goods are not understandable or achievable except through the exercise of the virtues mentioned above. The situation is different for external goods. Even if the possession and exercise of the virtues by researchers can allow them or the institution in which they work to obtain them, this also depends to a considerable extent on other factors. In particular, by the institution's relations with other companies and organisations and by its ability to communicate and sell its results externally (Scott 2003).

Corroboration of our perspective

The framework proposed in this paper may be corroborated by considering recent comprehensive surveys on personal values (Sagiv et al. 2017) and other studies that attempted to describe what is research and research performance.

Sagiv et al. (2017) propose a comprehensive review of the numerous existing studies on personal values, integrating different streams of research in psychology, sociology, management and political science. In their study, Sagiv et al. (2017) state: "*Individuals act in ways that allow them to express their important values and attain the goals underlying them.* Thus, understanding personal values means understanding human behaviour (Sagiv et al. 2017). In contrast to the numerous studies investigating the consequences of values, much less is known about the origin of values." In particular, Table 1 of Sagiv et al. (2017) provides a series of value definitions that may be attributed to the list of virtues we proposed in the previous section.

The framework we proposed is also in agreement with recent research on the main characterization and dimensions of the research activities developed in Åkerlind G.S. (2008) and Bazeley (2010).

Conclusions and further research

The conceptual framework developed in this paper allows us to identify (define) the *good* evaluation as the evaluation that is able to discriminate between good and bad research practices. Having characterized the research practice through "internal" and "external" goods, offers us the possibility to deepen our understanding about what is a good research practice and what is the role played by researchers in it. Reflecting on what is a "good" research practice, on what is the role of researchers in it, according to the typologies of researchers we propose (leader, good and honest researcher), may be extremely useful for many reasons.

Firstly, it offers a *self-assessment tool* for researchers, to understand the functions of their research activities, their motivations and where they are in their research practice. This is an important step towards the *improvement* of research practices and individuals involved in it.

Secondly, it helps institutions to collect and *describe* the main functions of the research practices (highlighting their special features) developed by its researchers, and their motivations, to include them in their *strategic plan*. This is a further important step for the *development* and *improvement* of the organizations involved.

To conclude, a "good" evaluation should take into account all the building constituents of a "good" research practice and should be able to discriminate between good and bad research practices, while *enforcing* the functions of good research practices.

These reflections, although at their infant stage, may be the starting point for a *paradigm shift* in the evaluation of research practices. From an evaluation focused on *products* towards an evaluation focused on the *functions* of research practices. This new way of evaluate might also contribute to improvement of the research practices itself, stimulating new innovative solutions thanks to the self-assessment of the research community, providing clearer views of the strategy, missions and functions of the groups involved in the research practices.

The effects of research policies on the management of research information in HEIs: evidence from Germany

Sophie Biesenbender[1] and Christoph Thiedig[2]

Abstract

The effects of research policies on research information management (RIM) in higher education institutions (HEI) are poorly studied, despite their practical and scientific relevance. Both, science governance and science studies require valid and quality-assured research information (RI), that is data and information on the processes, output and impact of research (e.g. with regard to staff, projects, publications, or patents). This paper presents first results from a comparative project on the patterns, developments and effects of research information governance in four European science systems. By focussing on the German case, we analyse the processes behind the institutional implementation of national research information policies, the rationales and factors affecting institutional prioritization as well as organizational and technical consequences. Survey evidence on the implementation of the German "Research Core Dataset" (RCD) illustrates that institutional implementation of the voluntary RI standard is currently being driven by internal considerations in HEIs and the strategic prioritization of RIM and less so by external factors (such as e.g. data requests in the RCD standard).

Introduction

Information on the processes, output and impact of research (in the following referred to as 'research information' – RI) is central to a number of actors and stakeholders of the science system. Policy making and governance at all levels (e.g. at the level of governments or research institutions) require both qualitative and quantitative information and data on staff, projects, publications, patents etc. at different levels of aggregation (e.g. research institutions or academic disciplines). In addition, research information is essential for analyses of the science system, its processes and performance. Transformed into STI indicators, the availability and quality of research information crucially influences the robustness and generalizability of scientometric analyses and their results. In this context, research institutions in many science systems constitute a central source of research information. They are important data providers and complement third-party publication or project databases.

In many science systems, we currently observe public policies to – directly or indirectly – regulate and professionalize the institutional management of research information and its reporting. These range from binding national assessment exercises to voluntary reporting standards.

Despite differences in terms of policy scope, obligation or strategic importance, these policies – once implemented – will have an impact on how research institutions collect, manage and report research information. While many science policies have been analysed in terms of e.g. behavioural effects in the scientific community or their impact on scientific excellence (see Rijcke et al. (2016) for a recent review), the consequences with regard to the handling and management of research information and – by extension – indicator quality have not been systematically studied so far.

This paper is part of an ongoing project to fill this gap and to study the effects of public RI policies on the institutional management of research information in higher education institutions (HEI). It is guided by the following question: What are the effects of public research policies on processes of institutional information management in HEIs? The analysis is part of an ongoing comparative project on the patterns, developments and effects of RI governance in four European science systems (Germany, Great Britain, Italy and the Netherlands). The project combines qualitative interviews with desk research and survey material. The empirical analysis presented in this paper focuses on the so-called "Research Core Dataset" (RCD) for the German science system – a voluntary definitional and reporting standard for research information (Biesenbender & Hornbostel, 2016). It reports evidence of a recent survey carried out among publicly funded German higher education institutions to assess the institutional effects of the RCD.

This research-in-progress paper is structured as follows. In the following section, we provide a discussion of the context and state-of-the-art. The next section includes a case description, and introduces the conceptual approach as well as the methods of analysis. The subsequent section presents the empirical results, followed by a short discussion and conclusion.

Context and state-of-the-art

In most science systems, research and higher education institutions are currently faced with a multitude of external and internal information requirements: publicly funded organizations usually have to report on their research staff, projects, publications, patents etc. towards governments and agencies (e.g. statistical offices) as well as to private actors (for e.g. rankings or comparative analyses) (Biesenbender & Hornbostel, 2016). In addition, research information is of strategic relevance also for internal purposes, such as the implementation of performance-based funding instruments (see Bryant et al., 2018; Hicks, 2012; Liefner, 2003; Orr, Jaeger, & Schwarzenberger, 2007).

Next to other important sources of research information (e.g. project repositories of funding organizations, publication databases by private companies), data and information collected, processed and reported by research institutions are central sources for assessments and evaluations of institutional and the science system's development and performance. In some science systems, such as the Netherlands, they are used for national research portals. In other cases (such as Great Britain or Italy) institutionally reported data are necessary for carrying out national evaluation schemes (Biesenbender, Petersohn, & Thiedig, 2019). Last, also science studies scholars often directly or indirectly rely on these data sources (e.g. by using official statistics, institutional publication records or project registers).

As a consequence of the growing relevance of institutional research information and the challenges associated with their collection and handling, research information management (RIM) systems and practices have increasingly become strategic aspects in the organization and steering of research institutions (Bryant et al., 2018, p. 45) The requirements of external and internal data requests have an impact on institutional data collection and management processes, which in turn crucially determine the quality of reported information and, hence, the robustness of evaluation and assessment results. In the recent past, these processes have received increasing political attention (see e.g. Butler, 2008; Geuna & Piolatto, 2016; Wilsdon et al., 2015). Moreover, horizontal networking has become an important activity for practitioners and data providers (e.g. through the non-for-profit association euroCRIS or initiatives like the CERIF standard; Vancauwenbergh, 2017).

Despite these dynamics, the governance of research information (from a policy-analytical perspective) is a poorly studied issue in the literature (but see Daraio et al. (2019)). There is only anecdotic evidence on the effects of RI policies on the institutional level. We do not know under what circumstances research institutions invest in the professionalization of RIM and how such processes can be steered by public policies. In sum, the way in which science policies influence the institutional handling of research information is an issue that has received little scholarly attention in the literature so far (Biesenbender, 2019). Therefore, this contribution offers, first, a classification of RI policies with regard to their provisions for institutional implementation. Second, we look at the effects of public RI policies on institutional practices to manage and report institutional research information by focussing on a recent survey on the Research Core Dataset for the German science system.

Empirical case, conceptual frame, and methods

Science systems differ with regard to the approaches to directly or indirectly regulate research information management at the institutional level and to affect comparability of data across research institutions. In some science systems, this occurs through the establishment of national information systems or research portals or mandatory central evaluation schemes to be implemented through standard software. Others rely on voluntary definitional and reporting standards to harmonize the variety of information requests. In this paper, we employ a broad definition of RI policy. It includes any government policy that affects the institutional collection, processing and/or reporting of research information. This may refer to e.g. institutional adjustments in organizational structures, procedures (to collect, process, or report information) or software We suggest that public RI policies be broadly classified along two basic dimensions: First, their implications with regard to technical issues – Does the policy require or favour the implementation of specific software in research institutions (e.g. Current Research Information System – CRIS)? Second, financial relevance – Does the policy entail any financial implications for research institutions?

The ongoing project and this paper focus on national RI policies in four European science systems: Italy, the Netherlands, the UK and Germany.
